1975. The formation of dung-beds is effected by first marking out the dimensions of the plan, which should be six inches wider on all sides than that of the frame to be placed over it, and then, by successive layers of dung laid on by the fork, raising it to the desired height, pressing it gently and equally throughout. In general, such beds are formed on a level surface; but Knight's mode (fig. 375.) is to form a surface of earth as a basis, which shall incline to the horizon to the extent of fifteen degrees; on this he forms the dung-bed to the same inclination; and, finally, the frame, when placed on such a bed, if, as is usual, it be deepest behind, will present its glass at an angle of twenty degrees instead of six or eight, which is undoubtedly of great advantage in the winter season. This seems a very desirable improvement where light is an object, which it must be, in a high degree, in the case of the culture of cucumbers and melons, as well as in forcing flowers.

1976. Ashes are often mixed with the dung of hot-beds, and are supposed to promote the steadiness and duration of their heat; and at first to revite it, if somewhat decayed. Tan and leaves have also been used for the same purpose; and it is generally found that about one third of tan and two thirds of dung will form a more durable and less violent heat than a bed wholly of dung. The heat of dung-beds is revived by linings or collateral and surrounding walls or banks of fresh dung, the old dung of the bed being previously cut down close to the frame. These linings, as before observed, require less preparation than the dung for the beds. The dung-bed being formed, and having stood two or three days with the frame and lights placed over it to protect it from rain, is next to be covered with earth, of quality and in quantity according to the purpose to which it is to be applied. In severe weather, the sides of the bed are often protected by bundles of straw or faggots, which tend to prevent the escape of the heat.
1977. Collecting and forming composites for manure is an essential part of the economy of the garden, no less than of the farm. The following judicious observations on this subject, by Bishop, merit attention:

Without enumerating the various means that, with careful economy, may be used for increasing the stock of garden manure, such as collecting the urine of animals, chamber-lie, soap-suds, or mixing fresh soils of opposite qualities, I shall confine myself to a plain statement of a method I have practised for these several years past with much success. Situated the same as many others, to whom the produce of the stable-yard is the only allowance of dung that can conveniently be allotted for the garden, which, although even without the assistance of bog-earth, or other peculiar mixture for garden crops, without having its qualities altered by fermentation, or blended with substances of a heavier nature, would, in many cases, be more injurious than beneficial; I therefore, during the summer and autumn, have all the offal in the garden, such as weeds, leaves of strawberries and other vegetables, short grass, peats and asparagus haunch, with the foliage of trees and shrubs when newly shed, carefully collected into the heap. These are all turned over and mixed during the winter, that they may be sufficiently rotted to mix with the dung against the end of the season. I have also another heap formed with the prunings from gooseberry and currant bushes, fruit-trees, raspberry-shoots, clippings of box-edgings, and loppings from shrubs; also the roots of greens and cabbages, which are generally burnt at two different periods in the year, viz. in spring and autumn; but previous to each burning, I endeavour to pare up all the coarse grasses around the garden, with a portion of the soil adhering thereto, and whenever these are sufficiently dried, have them collected to the heap intended to be burnt. The fire is kindled at a convenient distance from the heap, and a portion of such as burn most easily is first applied, until the fire hath gained a considerable power. After this, the process of burning is continued, by applying lighter and heavier substances alternately, that the one may preserve the action of the fire, and the other prevent it from reducing them too much to ashes. When the whole are thus consumed, a quantity of mould is thrown over the heap to prevent the fire from breaking through; and whenever it can be broke into with safety, it is then mixed up into a dunghill with the rotted vegetables, moss-earth, and stable-yard dung, in such proportions as is likely to ensure a moderate fermentation, which is generally completed in three or four weeks; at which time I think, it is most advantageously applied, in having it carried to the ground, and instantly dug in.

1978. Liquid manures are highly approved of by many cultivators, and especially by Knight. They are formed by infusing rich dungs, as those of fowls, sheep, pigs, &c. or blood, in three or four times their bulk of water; and the application of the extract so procured is made at the usual seasons of watering, taking care to apply it only to the roots. Knight applies this mode of manuring chiefly to plants in pots, and is convinced, from experience, that trees and shrubs may grow and bear fruit in very small pots, if abundantly supplied with nourishment in this manner. (Hort. Trans. vol. ii. p. 127.) For some plants, as the pine, vine, cauliflower, cucumber, and others which gardeners consider as gross feeders, liquid manures may be applied during their full vigor of growth; but the practice, we think, would be dangerous, if so applied to culinary or fruit-bearing plants in general, as producing too great excitement.

1979. Collecting and forming composites for mould. Composts are mixtures of several earths, or earthy substances or dungs, either for the improvement of the general soil under culture; or for the culture of particular plants.

1980. In respect to composites for the amendment of the general soil of the garden, their quality must depend on that of the natural soil; if this be light, loose or sandy, it may be assisted by the addition of heavy loams, clays, &c. from ponds and ditches, and the cleansing of sewers, &c. On the other hand, heavy, clayey, and all stubborn soils, may be assisted by light composites of sandy earth, drift, and sea-sand, the shovellings of turnpike-roads, the cleansing of streets, all kinds of ashes, rotten tanners’ bark, rotten wood, and sawdust, and other similar light opening materials that can be most conveniently procured.

1981. Composts for particular plants may be reduced to light sandy loam from old pastures; strong loam approaching nearly to brick-earth from the same source; peat-earth from the surface of heaths or commons; bog-earth from bogs or morasses; vegetable earth decayed leaves, stalks, cow-dung, &c.; sand, either sea-sand, drift-sand, or powdered stone, so as to be as free as possible from iron, lime-rubbish; and lastly common garden-earth. There are no known plants that will not grow or thrive in one or other of these earths alone or mixed with some other earth, or with rotten dung, or leaves. Nurserymen, whose practice may be considered a safe criterion to judge from, have seldom more than three sorts of earth: loam, approaching to the qualities of brick-earth; peat or bog-earth, from heaths or morasses; and the common soil of their nursery. With these, and the addition of a little sand for striking plants, some sifted lime-rubbish for succulents, and some well rotted cow-dung for bulbs and some sorts of trees, they contrive to grow thousands of different species in as great perfection (taking the difference between plants in pots and plants in the free soil and air) as in their native countries, and many, as the pine, vine, camellia, rose, &c. in a superior manner.

1982. Practical limit to ingredients for composites. Cushing, one of the best writers on the propagation of exotics, observes, “Loam, peat, and sand, seem to be the three simples of nature, if I may so call them, most requisite for our purpose; to which we occasionally add, as mollifiers, vegetable or leaf mould, and well rotted dung; from the judicious mixture and preparation of which, composites may be made to suit plants introduced from any quarter of the globe.” (Exotic Gardener, p. 153. 1814.) Sweet (Botanical Cultivator, 1820.) concurs in this opinion. See also Haynes On Collecting and Forming Composts, &c. 1821.
1983. Preparation of composites. The preparation requisite for the heavy and light composites for general enrichment, and of the above different earths, consists in collecting each sort in the compost-ground, in separate ridges of three or four feet broad and as high, turning them every six weeks or two months for a year or a year and half before they are used. Peat-earth being generally procured in the state of turves full of the roots and tops of heath, requires two or three years to rot; but, after it has lain one year, it may be sifted, and what passes through a small sieve will be found fit for use. Some nurserymen use both these loams and peats as soon as procured, and find them answer perfectly for most plants; but for delicate flowers, and especially bulbs, and all florists' flowers, and for all composites in which manures enter, not less than one year ought to be allowed for decomposition, and what is technically called sweetening. The French gardeners allow for their rich orange-tree composites from three to six years.

1984. The compost-ground may be placed in any situation concealed from the general view, but at the same time exposed to the free action of the sun, air, and rain. Its size will depend on that of the garden, and on the sorts of culture for which the moulds are adapted. It should generally form a part of the parallelogram enclosure used as hot-bed ground, and where there are hot-houses, both should be situate as near them as possible.

Sect. II. Operations of Propagation.

1985. The operations of propagation are among the most curious and difficult in gardening. As already observed (890.), plants are universally propagated by seed, but partially also by germs or bulbs, suckers, runners, slips, and offsets; and artificially by layers, inarching, grafting, budding, and cuttings.

Subsect. 1. Propagation by natural Methods.

1986. By seed. Here the first consideration is to make sure of live seeds; for some, as we have seen (717. to 722.) lose their vitality very early after being gathered, while others retain it only for one or perhaps two seasons; some seeds also are injured, and others are improved by keeping. The size of seeds requires also to be taken into consideration, for on this most frequently depends the depth which they require to be buried in the soil; the texture of their skin or covering must be attended to, as on this often depends the time they require to be buried in the soil previously to germination. On the form and surface of the outer coating of seeds sometimes depends the mode of sowing as in the carrot, and on their qualities in general depends their liability to be attacked by insects. The nature of the offspring expected and the proper climate, soil, and season require also to be kept in view in determining how, where, when, and in what quantity any seed must be sown. Such are the general considerations, their particular applications will afterwards occur.

1987. By germs or bulbs. These, whether cauline or radical, require in general to be planted immediately or soon after removal from the parent plant, in light earth about their own depth from the surface. Matured bulbs may be preserved out of the soil for some months, without injury to their vitality; but infant bulbs are easily dried up and injured when so treated.

1988. By offsets. This mode is not very easily distinguished from the foregoing and following, and seems in a strict sense only applicable to young radical bulbs, which, when separated or taken off from the parent roots, are termed offsets.

1989. By slips. These are shoots (fig. 376. a) which spring from the collar or the upper part of the roots of herbaceous plants, as in auricula, and under shrubs, as thyme, &c. The shoot, when the lower part from whence the roots proceed begins to ripen or acquire a firm texture, is to be slipped or drawn from the parent plant so far as to bring off a heel or claw of old wood, stem, or root, to which generally some roots, or rudiments of roots, are attached. The ragged parts and edges of this claw or rough section are then to be smoothed with a sharp knife, and the slip planted in suitable soil, and shaded till it strikes root afresh, or appears to have recovered from the effects of amputation.

1990. By division of the plant. This mode is adopted with many species, as most perennial grasses, the daisy, polyanthus, and a great variety of others. The plant is taken
up, and the earth shaken from its roots; the whole is then separated, each piece containing a portion of root and stem, which may be planted without farther preparation.

1891. By runners (fig. 376. c). With certain species this is a very convenient and sure mode of propagation. All that is requisite, is to allow the plantlet on the shoot or runner to be well rooted before being separated from the parent. It may then be planted where it is finally to remain.

1892. By suckers. (fig. 376. b). These are merely runners under ground; some run to a considerable distance, as the acacia, narrow-leaved elm, sea-limegrass, alkekengi, &c.; others are more limited in their migrations, as the lilac, syringa, Jerusalem artichoke, saponaria, &c. All that is necessary is to dig them up, cut off each plantlet with a portion of root, after which its top may be reduced by cutting off from one fourth to one half of the shoot, in order to fit it to the curtailed root, and it may then be planted, either in the nursing-department, or, if a strong plant, where it is finally to remain.

Subsect. 2. Propagation by Layering.

1893. Layers, as we have already observed (§40.) are indicated by nature, and we shall here point out the improvements of art and their applications. The roots in natural layers are produced by the stimulus of the moist earth on which the shoots, from the nature of the tree or plant, or accidental causes, recline; art increases the natural stimuli, and adds others, especially that of diminishing the resources of the shoot in the parent plant, by incision or fracture.

1894. Season. In general, the operation of layering in trees and shrubs is commenced before the ascent of the sap, or delayed till the sap is fully up, and thence the two seasons are early in spring or in midsummer. Autumn and winter are resorted to for convenience in extensive concerns. The shoot, or extremity of the shoot, intended to become a new plant, is half separated from the parent plant, at a few inches' distance from its extremity, and while this permits the ascent of the sap at the season of its rising, the remaining half of the stem being cut through and separated, forms a dam or sluice to the descending sap, which, thus interrupted in its progress, exudes at the wound in the form of a granulul protuberance, which throws out roots. If the cut or notch in the stem does not penetrate at least half way through, some sorts of trees will not form a nucleus the first season; on the other hand, if the notch be cut nearly through the shoot, a sufficiency of albuminum or soft wood is not left for the ascent of the sap, and the shoot dies. In delicate sorts it is not sufficient to cut a notch merely, because in that case, the descending sap, instead of throwing out granulated matter in the upper side of the wound, would descend by the entire side of the shoot; therefore, besides a notch formed by cutting out a portion of bark and wood, the notched side is slit up at least one inch, separating it by a bit of twig, or small splinter of stone or potsherd.

1895. Manipulation. Shoots when layered are often cut and mangled at random (fig. 377. a, b, c), or buried insufficiently, or so deep in the soil (d) that they throw out but few roots; or not placed upright (e), by which they make unsightly plants. In order to give some sort of principle to go upon, it should be remembered, that the use of the notch is to prevent the heel or part intended to throw out granulous matter from being bruised, which it generally is, by the common practice of performing this operation by one cut sloping upwards; and that the use of the slit is to render it more difficult for the descending sap to return from the extremity of the heel. In conformity with this idea, Knight recommends taking up the shoot after it has grown some time, and cutting off a ring of bark below the notch and slit, so as completely to hinder the return of the sap, and thereby force the shoot to employ it in forming roots. (Hort. Trans. vol. i. 256.) In burying an entire shoot (f) with a view to induce shoots to rise from every bud, notches alone are sufficient without either slitting or ringing. The use of the splinter of wood, or bit of tile or potsherd, is partly to prevent the union of the parts when the bent position of the shoot is not sufficient, and partly, and in some cases principally, to act as a stimulus, like the bottom and sides of pots. On what principle it acts as a stimulus,
has not, we think, been yet determined, but its effects have long been very well known to gardeners. In all cases the layer must be held firmly in its place by hooked pegs. The operation of layering is performed on herbaceous plants as well as trees; and the part to become the future plant is, in both cases, covered with soil about a third of its length.

1996. Layering by twisting, ringing, piercing, and wiring the shoot intended for the future plant is also occasionally practised.

1997. Piercing is performed with an awl, nail, or penknife, thrust through two or three times in opposite directions at a joint; from which wounds, first, granulated matter oozes, and finally, fibres are emitted.

1998. Ringing is cutting off a small ring of bark and part of the wood, by which the return of the sap being wholly prevented, it is, therefore, as it were, compelled to form roots. Care must be taken, however, that the ring does not penetrate far into the wood, otherwise the sap will be prevented from ascending in the first instance, and the shoot killed.

1999. Wiring is performed by twisting a piece of wire round the shoot at a joint, and pricking it at the same time with an awl on both sides of the wire. It is evident that all these methods depend on the same general principle, that of permitting the ascent of the sap through the wood, but checking its descent by cutting off or closing the vessels of the bark.

2000. Layers which are difficult to strike may be accelerated by ringing. Ringing is an excellent method for making layers of hard-wooded plants strike root with greater certainty, and in a smaller space of time than is attained in any other way. The accumulated vegetable matter in the callus, which is formed on the upper edge of the ring, when brought into contact with the soil, or any material calculated to excite vegetation, readily breaks into fibres and roots. (Hort. Trans. iv. 558.)

2001. In layering trees in the open—garden, whatever mode be adopted, the ground round each plant intended for laying, must be dugged for the reception of the layers; then making excavations in the earth, lay down all the shoots or branches properly situated for this purpose; pegging each down with a peg or hooked stick; laying also all the proper young shoots on each branch or main shoot, fixing each layer from about three or four to six inches deep, according as they admit, and moulding them in at that depth, leaving the tops of every layer out of ground from about two or three to five or six inches, according to their length, though some shorten their tops down to one or two eyes. Observe also to raise the top of each layer somewhat upright, especially tongue or slit layers, in order to keep the slit open. As the layering is completed, level in all the mould finally, and equally in every part close about every layer, leaving an even, smooth surface, presenting only the tops of each layer in the circumference of a circle, and the stems or stools in the centre. Sometimes the branches of trees are so inflexible, as not to be easily brought down for laying; in which case they must be plashed, making the gash or cut on the upper side; and when they are grown too large for plashing, or that the nature of the wood will not bear that operation, they may be thrown on their sides, by opening the earth about their roots, and loosening or cutting all those on one side, that the plant may be brought to the ground to admit of laying the branches.

2002. Layering plants in pots. When layers are to be made from green-house shrubs, or other plants in pots, the operation should generally be performed either in their own pots, or in others placed near that of the stool to receive the layer.

2003. General treatment. After laying in either of the above methods, there is no particular culture requisite, excepting that of keeping the earth as much as possible of uniform moisture, especially in pots; and watering these in the open air in dry weather.

2004. Management of stools. When the layers are rooted, which will generally be the case by the autumn after the operation is performed, they are all cleared from the stools or main plants, and the head of each stool, if to be continued for furnishing layers, should be dressed; cutting off all decayed and scraggy parts, and digging the ground round them. Some fresh rich mould should also be worked in, in order to encourage the production of the annual supply of shoots for layering.

2005. Chinese layering. The Chinese method of propagating trees by first ringing, or nearly so, a shoot, and then covering the ringed part with a ball of clay and earth, covered with moss or straw, is obviously on the same general principle as layering; and is better effected in this country by drawing the shoot through a hole in a pot (such a pot as \textit{fig. 175.}); ringing it to the extent of three fourths of its circumference, near the bottom or side of the pot, and then the pot, being supported in a proper position, and filled with earth, it may be watered in the usual way. Some plants difficult to strike, and for which proper stocks forarching are not conveniently procured, are thus propagated in the nursery hot-houses.

2006. Removal of the rooted layer or plantlet. Though layers of trees completed early
in spring, and of herbaceous plants after the season of their flowering, are generally fit to remove from the parent plant the end of the succeeding autumn; yet many sorts of American trees require two years to complete their roots. On the other hand, some sorts of roses and deciduous shrubs, if their present year’s wood be laid down when about half grown, or about the middle of August, it will produce roots, and be fit to separate the succeeding autumn.

**Subsect. 3. Propagation by Inarching.**

2007. *Inarching* may be described as a sort of layering, by the common or slit process, in which the talus or heel intended to throw out fibres, instead of being inserted in the soil, is inserted in the wood, or between the wood and bark of another plant, so as to incorporate with it. It evidently depends on the same general principles as layering; and all the difference is, that the granulated matter which exudes between the bark and the wood of the talus or heel, instead of throwing out fibres, unites with the wood of the stock or plant to which it is attached, forming a solid ligneous union, which, when the layer or shoot is separated from the mother plant, supplies it with nourishment as the fibres do the common layer. It is the most certain mode of propagation with plants difficult to excite to a disposition for rooting; and when all other modes fail, this, when a proper description of stock or basis is to be found, is sure to succeed. Professor Thouin (Cours Complet d’Agriculture, &c. art. Greffe) has enumerated thirty-seven varieties of inarching; but they may all be reduced to two, crown inarching, in which the head of the stock is cut off (fig. 378. a), and side inarching (b and c), in which the head of the stock is left on. With young hardy trees, the first mode is reckoned the best, as the whole effort of the stock is thereby directed to the nourishment of the inarched shoot; the other is resorted to in propagating delicate trees, and for filling up blanks in branches, and other purposes.

2008. *Preparatory measures.* The stocks designed to be inarched, and the tree from which the layer or shoot is to be bent or arched towards them, and put in or united, must be placed if in pots, or planted if in the open soil, near together. Hardy trees of free-growing kinds should have a circle of stocks planted round them every year in the same circumference, every other one being inarched the one year, and when removed, their place supplied by others, so that there will always be, by this practice, stocks of one year’s standing ready to receive the shoot. If the branches of the tree are too high for stocks in the ground, they should be planted in pots, and elevated on posts or stands, or supported from the tree, &c.

![Diagram of Propagation by Inarching](image)

2009. *Manipulation.* Having made one of the most convenient branches or shoots approach the stock, mark on the body of the shoot the part where it will most easily join to the stock; and in that part of each shoot pare away the bark and part of the wood two or three inches in length, and in the same manner pare the stock in the proper place for the junction of the shoot; next make a slit upwards in that part of the branch or shoot, as in layering, so as to form a heel, but more of a tongue shape than in layering, and make a slit downward in the stock to admit it. Let the parts be then joined, slipping the tongue of the shoot into the slit of the stock, making both join in an exact manner, and tie them closely together with bass. Cover the whole afterwards with a due quantity of tempered or grafting clay or moss. In hot-houses, care must be taken not to disturb the pots containing the plants operated on.

2010. *Seasons for the operation.* Inarching, like layering, is commonly performed in
spring, and in general cases, the union is effected in four or five months, when the layer or inarched shoot may be separated from the mother plant. This must be done with a very steady hand, so as not to loosen or break out the adhering shoot, sloping it off downwards, close to the stock; and if the head of the stock was not cut down at the time of inarching, it must now be cut off in a sloping direction close to the union; and all the old clay and bandage cleared away and replaced with new, to remain a few weeks longer till the adhesion is complete, when it may be finally removed. In some cases, however, the inarched shoot requires to remain two years, during the whole of which period, it should be carefully covered to exclude the air from the wounds; nor must the binding be removed more than once during that period for fear of disturbing the cicatrising parts.

2011. Inarching a branch or shoot on the same tree (fig. 378, b) is frequently a very convenient mode of filling up vacancies in trees; in which case it is generally performed without heading down. Knight adopted this practice on a peach-tree, for a very ingenious purpose, that of procuring returning or concocted sap to swell and ripen the fruit.

"In the last season (1812), a peach-tree in my garden, of which I was very anxious to see the fruit, had lost, by the severity of the weather, all its blossoms, except two, which grew upon leafless branches: I was very desirous to preserve these, as well as to ascertain the cause why the peach and nectarine, under such circumstances, fail to acquire maturity. The most probable cause, according to my hypothesis, appeared to be the want of returning sap (which the leaves, if existing, would have afforded), and the consequent morbid state of the branch; I therefore endeavoured to derive the necessary portion of returning sap from another source. To obtain this object, the points of the branches, which bore fruit, were brought into contact with other branches of the same age that bore leaves; and a part of their bark, extending in length about four times their diameters, was pared off immediately above the fruit. Similar wounds were then made upon the other branches, with which these were brought into contact; and the wounded surfaces were closely fitted; and tightly bound together. An union soon took place; and the fruit, apparently in consequence of it, acquired the highest state of maturity and perfection." Inarching, like grafting, may be applied to various curious and useful purposes (c, d). Harte mentions that the hornbeam-hedges, in some parts of the Netherlands, were worked in the lozenge form (d), and that by removing the bark at each intersection, the whole had become united as if one tree. Some curious examples of inarching and grafting combined are to be seen in the Jardin des Plantes.

2012. Inarching herbaceous vegetables may, in almost all solid or sub-solid stalked plants, whether annual or of longer duration, be performed with equal certainty as in ligneous kinds. The vine of the cucumber may be inarched on that of the gourd, the love-apple on the potato, &c. (Baron Tschoudi.)

**Subsect. 4. Propagation by Grafting.**

2013. Grafting is a mode of propagation applicable to most sorts of trees and shrubs; but not easily to very small under-shrubs, as heath or herbaceous vegetables. It is chiefly used for continuing varieties of fruit-trees. A grafted tree consists of two parts, the scion and the stock; their union constitutes the graft, and the performance of the operation is called grafting. The scion is a part of the living vegetable, which, united or inserted in a stock or other vegetable of the same nature, identifies itself with it, and grows there as on its natural stem and roots.

2014. The end of grafting is, 1st. To conserve and multiply varieties and subvarieties of fruit-trees, endowed accidentally or otherwise with particular qualities, which cannot be with certainty transferred to their offspring by seeds, and which would be multiplied too slowly, or ineffectually, by any other mode of propagation. 2. To accelerate the fruitification of trees, barren as well as fruit-bearing; for example, suppose two acorns of a new species of oak, received from a distant country; sow both, and after they have grown one or two years, cut one of them over, and graft the part cut off on a common oak of five or six years' growth; the consequence will be that the whole nourishment of this young tree of five years' growth being directed towards nourishing the scion of one or two years', it will grow much faster, and consequently arrive at perfection much sooner than its fellow, or its own root left in the ground. A French author found the advantage of this practice in the case of a new species of ash, to be as five to one in point of height. (Cours Complet d'Agriculture, &c. art. Greffe.) The third use of grafting is to improve the quality of fruits; the fourth to perpetuate varieties of ornamental trees or shrubs; and the fifth to change the sorts of fruit on any one tree and renew its fruitfulness.

2015. The theory of grafting may be reduced to the following particulars:

2016. To graft or unite only varieties of the same species; species of the same genus; and by extension, genera of the same natural family. Unless this union of natures be attended to, success will not attend the operation.

2017. To observe the analogies of trees, as to the periods of the movement of their sap; in the permanence or deciduous duration of their leaves; and the qualities of the juices
their fruits, in order to estimate the probable advantage of grafting a fruit of any particular flavor on another of similar or different qualities.

2018. To unite exactly the inner bark of the scion with the inner bark of the stock in order to facilitate the free course of the sap.

2019. To make choice of the proper season, and perform the operation with celerity.

2020. Any scion will not succeed on any stock. Professor Thouin observes, that the historians and poets of antiquity have written, and the moderns repeated on the faith of others, that every scion will take on any sort of stock, provided there be a resemblance in their barks. Thus Pliny, Varro, Columella, &c. speak of apples and vines grafted on elms and poplars; and Evelyn mentions, that he saw a rose grafted on an orange-tree in Holland. The ancients acknowledged, however, that such grafts were but of very short duration. "The result of numerous experiments which we have made," observes the professor, "proves that if any one of these grafts seems at first to succeed, they all perish more or less promptly."

2021. Certain species of trees, and certain varieties of fruits, take more easily on some stocks than on others. Sometimes the cause is known, and at other times we are ignorant of it. Thus the platanus-leaved maple will not receive the scions of any species of its genus; the reason of which may perhaps be deduced from its milky sap, which indicates an organisation different from its congers. In like manner, the common walnut takes with difficulty on the late walnut; because the times of the motion of their sap do not coincide. But why certain varieties of pear succeed better on the quince than on the seedling, and others better on the seedling than on the quince, cannot so easily be accounted for. Such anomalies are frequent, and make part of the practical science of gardeners; of so much more the importance, because less subjected to general laws. (Cours Complet, &c. art. Greffe.)

2022. Grafting may be performed on all herbaceous vegetables with solid stems. The dahlia roots are frequently grafted in this country, and sometimes the stems are grafted or inarched. Baron Tschoudi at Strasbourg, and other physiologists at Paris, have grafted melons on cucumbers, love-apples on potatoes, cauliflower on cabbages, &c. and made other similar unions with perfect success. Many of them are detailed in Essai sur la Greffe de l'Herbe, &c. by the Baron Tschoudi, 1819.

2023. Grafting may be performed with the current year's shoots, or with shoots of several years' growth. This is evident from the general principles of the art, as well as from experience. Knight, the Baron Tschoudi, and others, have grafted young shoots in leaf; and Professor Van Mons, at Brussels, has grafted an entire tree, 15 feet high, on the stump of another of similar diameter. (Neill, in Horticultural Tour, 310.)

2024. Influence of the stock. The stock does not change the character of the species of tree, which may be grafted on it; nor even that of the variety, if the connection between the stock and scion is intense: but by a particular choice of stocks, the tree is often modified differently in the dimensions of its parts; in its general aspect; in the flavor and size of its fruit, though perhaps in a very slight degree; and in the duration of its existence.

2025. The nature of the fruit is to a certain extent affected by the nature of the stock. Miller says decidedly, "that crab-stocks cause apples to be firmer, to keep longer, and to have a sharper flavor; and he is equally confident, that if the breaking pears be grafted on quince-stocks, the fruit is rendered gritty or stony, while the melting pears are much improved by such stocks. This, according to Neill, is scarcely to be considered as inconsistent with Lord Bacon's doctrine, 'that the scion overruleth the graft quite, the stock being passive only'; which, as a general proposition, remains true; it being evident, that the scion, bud, or inarched shoot is endowed with the power of drawing or forming from the stock that peculiar kind of nourishment which is adapted to its nature, and that the specific characters of the ingrafted plant remain unchanged, although its qualities may be partially affected." (Ed. Encyc. art. Hort.)

2026. Fruitfulness and precocity produced by grafting. The effects produced upon the growth and produce of a tree by grafting, Knight observes, "are similar to those which occur when the descent of the sap is impeded by a ligature, or by the destruction of a circle of bark. The disposition in young trees to produce and nourish blossom-buds and fruit, is increased by this apparent obstruction of the descending sap; and the fruit of such young trees ripens, I think, somewhat earlier than upon other young trees of the same age, which grow upon stocks of their own species; but the growth and vigor of the tree, and its power to nourish a succession of heavy crops are diminished apparently by the stagnation in the branches and stock of a portion of that sap, which, in a tree growing upon its own stem, or upon a stock of its own species, would descend to nourish and promote the extension of the roots. The practice, therefore, of grafting the pear-tree on the quince-stock, and the peach and apricot on the plum, where extensive growth and durability are wanted, is wrong; but it is eligible wherever it is wished to diminish the vigor and growth of the tree, and where its durability is not thought important."
He adds, "When great difficulty is found in making a tree, whether fructiferous or ornamental, produce blossoms, or in making its blossoms set, when produced, success will probably be obtained in almost all cases, by budding or grafting upon a stock which is nearly enough allied to the graft to preserve it alive for a few years, but not permanently. The pear-tree affords a stock of this kind to the apple; and I have obtained a heavy crop of apples from a graft which had been inserted in a tall pear-stock, only twenty months previously, in season when every blossom of the same variety of fruit in the orchard was destroyed by frost. The fruit thus obtained was externally perfect, and possessed all its ordinary qualities; but the cores were black, and without a single seed; and every blossom had certainly fallen abortively, if it had been growing upon its native stock. The experienced gardener will readily anticipate the fate of the scion; it perished in the following winter. The stock, in such cases as the preceding, promotes, in proportion to its length, the early bearing and early death of the graft."

2027. Species and varieties of grafting. The chief modern writers on grafting are, Quintiney, Du Hamel, Rosier, and Professor Thouin, among the French; Mayer, Die-derich, Christ, and Sickler, among the Germans; Clarici and P. Re, among the Italians; and Miller, Curtis, and Knight, among the English. Professor Thouin has refined so much on the subject, as to have produced or enumerated above forty modes of grafting, besides a great many kinds of budding and inarching, named chiefly after eminent an cient and modern botanists and gardeners, as Pliny, Virgil, Quintiney, Miller, Adanson, &c. Most of these are, however, varieties of the ordinary species, and separated by such slender shades of difference, or so remotely connected with utility (as the Greffe Banks), that they do not appear of sufficient importance for admission here; and we shall, there fore, chiefly describe such varieties as have been long known and practised; which form the basis of all the others; and which every individual may vary according to his taste. The reader who would enquire further into the subject, may consult Curtis's Lectures on Botany, vol. iii. and Nouveau Cours Complet d'Agriculture, &c. tom. xvi. art. Greffe.

2028. Whip-grafting (fig. 379. a), or, as it is sometimes called, tongue-grafting, is the most generally adopted in nurseries for propagating fruit-trees. To effect this mode in the best style, it is desirable, that the top of the stock, and the extremity of the scions should be nearly of equal diameter. Hence this variety admits of being performed on smaller stocks than any other. It is called whip-grafting, from the method of cutting the stock and scions, sloping on one side so as to fit each other, and thus tied together in the manner of a whip-thong to the shaft or handle. The scion and stock being cut off obliquely at corresponding angles, as near as the operator can guess, then cut off the tip of the stock obliquely or nearly horizontally; make now a slit nearly in the centre of the sloped face of the stock downwards, and a similar one in the scion upwards. The tongue or wedge-like process, forming the upper part of the sloping face of the scion, is then inserted downwards in the cleft of the stock; the inner barks of both being brought closely to unite on one side so as not to be displaced in tying, which ought to be done immediately with a riband of bass, brought, in a neat manner, several times round the stock, and which is generally done from right to left, or in the course of the sun. The next operation is to clay the whole over an inch thick on every side, from about half an inch or more below the bottom of the graft, to an inch over the top of the stock, finishing the whole coat of clay in a kind of oval globular form, closing it effectually about the scion and every part, so as no light, wet, nor wind may penetrate; to prevent which is the whole intention of claying. It may be added, that the whip-grafting of Lawson, and other old horticultural writers, was then practised without a tongue, which addition gave rise to the latter term. The French mode of whip-grafting differs from the English in their never paring more off the stock; however large, than the width of the scion (fig. 380. e, f, g). In both modes, the stock is sometimes not shortened down to the graft, but a few inches left to serve as a prop to tie the shoots proceeding from the scion; or even to admit of fastening the ligatures used in the operation more securely. In either case, if the graft has succeeded, this appendage is cut off at the end of the season.

2029. Cleft-grafting (fig. 379. b) is resorted to in the case of strong stocks, or in heading down and re-grafting old trees. "The head of the stock or branch (which we may suppose to be two or three inches in diameter) is first cut off obliquely, and then the
sloped part is cut over horizontally near the middle of the slope; a clef nearly two inches long is made with a stout knife or chisel in the crown downwards, at right angles to the sloped part, taking care not to divide the pith. This clef is kept open by the knife. The scion has its extremity for about an inch and half, cut into the form of a wedge, it is left about the eighth of an inch thicker on the outer or back side, and brought to a fine edge on the inside. It is then inserted into the opening prepared for it; and the knife being withdrawn, the stock closes firmly upon it." If it be intended to graft any pretty large stocks or branches by this method, two or more scions may be inserted in each. The stock being prepared by cutting over as above, cleave it across in two places parallel and at a small distance apart, and insert a scion in each clef; or by cutting or sawing the head off horizontally, and smoothing the section, a radiated series of clefs may be made, and scions inserted in each.

2030. Crown-grafting is another mode adopted for thick stocks, shortened branches, or headed down trees. It is sometimes called grafting in the bark or rind, from the scion being inserted between the bark and wood. This mode of grafting is performed with best effect, somewhat later than the others, as the motion of the sap renders the bark and wood of the stock much more easily separated for the admission of the scions. In performing the operation, first cut or saw off the head of the stock or branch, horizontally or level, and pure the top smooth; then having the scions, cut one side of each flat and somewhat sloping, an inch and half long, forming a sort of shoulder at the top of the slope, to rest upon the crown of the stock; and then raise the rind of the stock with the ivory wedge, forming the handle of the budding-knife (fig. 110.); so as to admit the scion between that and the wood two inches down; which done, place the scion with the cut side next the wood, thrusting it down far enough for the shoulder to rest upon the top of the stock; and in this manner be may be three, four, five, or more scions, in one large stock or branch. It is alleged as a disadvantage attending this method in exposed situations, that the ingrafted shoots for two or three years are liable to be blown out of the stock by violent winds; the only remedy for which is tying long rods to the body of the stock or branch, and tying up each scion and its shoots to one of the rods.

2031. Side-grafting (fig. 379. c) resembles whip or tongue grafting, but differs in being performed on the side of the stock without bending down. It is practised on wall trees to fill up vacancies, and sometimes in order to have a variety of fruits upon the same tree. Having fixed upon those parts of the branches where wood is wanting to furnish the head or any part of the tree, there slope off the bark and a little of the wood, and cut the lower end of the scions to fit the part as near as possible, then join them to the branch, tie them with buss, and clay them over.

2032. Saddle-grafting is performed by first cutting the top of the stock into a wedge-like form, and then splitting up the end of the scion and thinning off each half to a tongue shape; it is then placed on the wedge, embracing it on each side, and the inner barks are made to join on one side of the stock, as in cleft-grafting. This is a very strong and handsome mode for standard-trees when grafted at the standard-height. It is also desirable for orange-trees, and rose-standards, as it makes a handsome finish, covering a part of the stock, which by the other methods, long remains a black scar, and sometimes never becomes covered with bark. The stocks for this purpose should not be much thicker than the scions, or two scions may be inserted.

2033. A local variety of saddle-grafting (fig. 379. d, e, f) is thus described by Knight, as practised upon small stocks, and almost exclusively in Herefordshire. It is never attempted till the usual season of grafting is passed, and till the bark is readily detached from the alburnum. The head of the stock is then taken off by a single stroke of the knife obliquely, so that the incision commences about a diameter below the point where the me-
dulla appears in the section of the stock, and ends as much above it, upon the opposite side. The scion, which should not exceed in diameter half that of the stock, is then to be divided longitudinally, about two inches upwards from its lower end, into two unequal divisions, by passing the knife upwards just in contact with one side of the medulla. The stronger division of the scion is then to be pared thin at its lower extremity, and introduced, as in crown-grafting, between the bark and wood of the stock; and the more slender division is fitted to the stock upon the opposite side. The scion consequently stands astride the stock, to which it attaches itself firmly upon each side, and which it covers completely in a single season. Gifts of the apple and pear rarely ever fail in this method of grafting, which may be practised with equal success with young wood in July, as soon as that has become moderately firm and mature.

2034. A subvariety of saddle-grafting (fig. 381.), applicable to very slender shoots, is practised by Knight, who gives the rationale and manipulation in his usual masterly manner. As this mode has rarely “or never been properly executed, it will be necessary that I describe the motion of the sap as I conceive it to be, at the period when grafts are most advantageously inserted. The graft first begins its efforts to unite itself to the stock just at the period when the formation of a new internal layer of bark commences in the spring; and the fluid, which generates this layer of bark, and which also feeds the inserted graft, radiates in every direction from the vicinity of the medulla, to the external surface of the albumen. The graft is of course most advantageously placed when it presents the largest surface to receive such fluid, and when the fluid itself is made to deviate least from its natural course. This takes place most efficiently, when a graft of nearly equal size with the stock is divided at its base and made to stand astride the stock, and when the two divisions of the graft are pared extremely thin, at and near their lower extremities, so that they may be brought into close contact with the stock (from which but little bark or wood should be pared off) by the ligature. I have adopted this mode chiefly in grafting cherry-trees, and I have rarely ever seen a graft fail, even where the wood has been so succulent and immature as to preclude every hope of success by any other mode.” (Hort. Trans. v. 147.)

2035. Shoulder, or chink-grafting, is performed with a shoulder, and sometimes also with a stay at the bottom of the slope. It is chiefly used for ornamental trees, where the scion and stock are of the same size (fig. 380. a, b, c, d).

2036. Root-grafting (fig. 380. h) is sometimes performed in nurseries on parts of the roots of removed trees, when the proper stocks are scarce; and in which ease, the root of the white thorn has been resorted to as a stock both for the apple and pear. In general, however, a piece of the root of the tree of the same genus is selected, well furnished with fibres, and a scion placed on it in any of the ordinary ways for small stocks. Thus united, they are planted so deep as to cover the ball of clay, and leave only a few eyes of the scion above ground. Some gardeners have thought, that in this way, the plant must preserve a near resemblance to the parent tree; but Abercrombie remarks, that though it is an expeditious way of obtaining a new plant, such a graft cannot be materially different from a cutting or layer.

2037. A variety of root-grafting, practised by Knight, is thus described. “Transplanting, many years ago, some pear-stocks from a seed-bed, of which the soil was soft and deep, I found that the first emitted roots of many of them descended a foot or more perpendicularly into the earth, before they divided into any lateral ramifications: and as I did not like to replant the young trees, with such an inconvenient length of perpendicular root, I cut off about six inches from each. The amputated parts were then accurately fitted and bound, as in splice or whip-grafting, to scions of pear-trees, which were selected as nearly as possible of the same size; and the roots, with their attached branches, were deposited in the ground as cuttings, so deep, that the whole of the root, and about an inch of the scion, were covered. The soil was then drawn up with the hoe on each side of the plants, which were placed in rows, so that one bud only of each graft was above the soil, and another just within it. These grafts succeeded perfectly well; and I have subsequently repeated the same experiment with equal success upon the apple, the plum, and the peach. In the greater part of these experiments, the roots were perfectly cleansed from mould by washing, before they were fitted to the graft, and were then placed in wet moss, till a sufficient number were ready to be carried to the nursery; a common dibber only was employed in planting them; but the mould was washed into the holes with water, to close it well round the roots, and to supply the place of the clay used in other methods of grafting.” (Hort. Trans. vol. i. p. 289.) A variation of this
mode, consists in leaving that part of the tap-root not wanted with the removed tree undisturbed in the soil, and grafting on it there. Such root-grafts grow with uncommon vigor.

2044. 

Preparation of scions. Scions should be gathered several weeks before the season for grafting arrives; the reason is, that experience has shown that grafting may most successfully be performed, by allowing the stock to have some advantage over the graft in forwardness of vegetation. It is desirable that the sap of the stock should be in brisk motion at the time of grafting; but by this time the buds of the scion, if left on the parent tree, would be equally advanced; whereas the scions, being gathered early, the buds are kept back, and ready only to swell out when placed on the stock. Scions
of pears, plums, and cherries are collected in the end of January, or beginning of February. They are kept at full length, sunk in dry earth, and out of the reach of frost till wanted, which is sometimes from the middle of February to the middle of March. Scions of apples are collected any time in February, and put on from the middle to the end of March. In July grafting (2033.), the scions are used as gathered.

2045. The materials used in grafting are, a strong pruning-knife for cutting off the heads of the stocks previous to their preparation by the grafting-knife for the scion; a small saw for large stocks; and a penknife for very small scions; a chisel and mallet for cleft-grafting; bass-ribbands as ligatures; and grafting-clay.

2046. Grafting-clay is prepared either from stibby yellow or blue clay, or from clayey loam or brick-earth; in either case, adding thereto about a fourth part of fresh horse-dung, free from litter, and a portion of cut hay, mixing the whole well together, and adding a little water; then let the whole be well beaten with a stick upon a floor, or other hard substance; and as it becomes too dry apply more water, at every beating turning it over; and continuing beating it well at top till it becomes flat and soft. This process must be repeated, more or less, according as the nature of the clay may require to render it ductile, and yet not so tough as to be apt to crack in dry weather; for instance, it should be several times beaten the first day; and next morning repeat the beating, still moistening it with water, and by thus repeating the beating several times every day for two or three days, or every other day at least, for a week, it will be in proper order for use; observing that it should be prepared a week at least before it is used; but if a month, the better, keeping it moist. Some recommend salt to be mixed with the clay, and others ashes or lime-rubbish, or drift-sand; the object in these cases being to prevent its cracking with the sun; which, however, the horse-droppings, if well incorporated, will in general fully prevent.

2047. The grafting-clay of the French and Dutch, Onguent de St. Fiacre (St. Fiacre being the patron saint of gardening), is composed of half cow-dung, free from litter, and half fresh loam, intimately incorporated. They prefer this to all others for excluding the external air from wounds of every description, and ridicule the idea of certain complex compositions. Bosc (N. C. d'Ag. &c. tom. v. art. Enlubmen) observes of a noted English composition for healing wounds, that it is so "complicated and ridiculous in the eyes of those who have any knowledge of chemistry or natural philosophy, that it is a matter of astonishment how it could be proposed in our age."

2048. Substitutes for grafting-clay. Abercrombie and various authors mention resinous substitutes for clay, the details of which are given in the first edition of Miller's Dict. These substitutes are recommended for small and delicate trees, as camellias, daphnes, &c. and are composed of wax and pitch, pitch and tallow, tallow and oil, or a compound of turpentine, bees'-wax, and rosin, at first melted together, and afterwards heated as wanted; care being taken not to apply it too hot. A coating laid on with a brush, to the depth of a quarter of an inch, is said to be less liable to crack than clay; and it is added, that when the full heat of summer arrives, the composition melts away of its own accord. This last circumstance, we must confess, appears a sufficient argument against its use, since its removal must depend on the weather, and not on the state of the graft. We have seen its use in Italy attended by such consequences. D. Powel, Esq. spreads it on shreds of brown paper; wraps these round the graft, and over them some bass ties. (Hort. Trans. v. 282.)

2049. The use of compositions for covering grafts is threefold; 1st. To prevent the evaporation of the sap from the wounds; 2d. The too sudden drying of the wood; and, 3d. The introduction of rain-water in the wound or cleft. It is evident, therefore, that whatever sort of clay or coating is adopted, much will depend on its immediate application, and instantaneous repair in future, wherever it cracks or falls off. In addition to claying, some nurserymen cover the clay with a coating of moss, to preserve a moderate degree of moisture and tenacity; and others, in the case of dwarf-trees grafted close to the ground, earth up the grafts for the same purpose. These practices suit particular cases, but are not generally necessary. Earthing up is one of the best accompaniments to claying, and should seldom be omitted when it can be adopted.

Subsect. 5. Propagation by Budding.

2050. Budding, or grafting by gems, consists, in ligneous plants, in taking an eye or bud attached to a portion of the bark, of different sizes and forms, and generally called a shield, and transporting it to a place in another, or a different ligneous vegetable. In herbaceous vegetables the same operation may be performed, but with less success. It may also be performed with buds of two or three years' standing, and on trees of considerable size, but not generally so. The object in view in budding is almost always that of grafting, and depends on the same principle; all the difference between a bud and a scion being, that a bud is a shoot, or scion, in embryo. In all other respects, budding is conducted on the same principles as grafting.

2051. A new application of budding has been made by Knight. It is that of transferring
"a part of the abundant blossom-buds from one tree to the barren branches of others."

He tried this first on roses, and afterwards on the pear and peach, with much success. In this way also he considers that fruit might be produced on yearling trees, not as matter of utility (as in supplying barren trees with blossom-buds), but as a curious experiment.

2052. Advantages of budding. Budded trees are generally two years later in producing their fruit than grafted ones; but the advantage of budding is, that where a tree is rare, a new plant can be got from every eye, whereas by grafting it can only be got from every three or four eyes. There are also trees which propagate much more readily by budding than grafting; and others, as most of the stone-fruits, are apt to throw out gum when grafted. When grafting has been omitted or has failed in spring, budding comes in as an auxiliary in summer.

2053. Season of budding. The operation of common budding is performed any time from the beginning of July to the middle of August; the criterion being the formation of the buds in the axille of the leaf of the present year. The buds are known to be ready by the shield or portion of bark, to which they are attached, easily parting with the wood. The buds preferred are generally those on the middle of a young shoot, as being neither so apt to run to wood as those at the extremity, nor so apt to lie dormant as those at the lower end. In some cases, however, the buds from the middle and extremity of the shoots are to be rejected, and those taken which are at the base of the annual shoots, as Knight (Hort. Trans. vol. iii. 135.) found in the case of the walnut-tree. Scalope-budding may be performed in spring, or at any season.

2054. Stocks for budding may, in general, be much smaller than for grafting, as the operation may be performed on the same year's shoot. But it may also be performed on shoots or stems of several years' growth, and in such, by inserting a number of buds, a complete tree may be formed at once. Scalope-budding may be performed on trees of considerable age.

2055. Choice of 'buds. For gathering the shoots containing the buds, a cloudy day or an early or late hour is chosen, on this principle, that the leaves being at these periods in a less active state of perspiration, suffer least from being separated from their parent plant. They are preserved fresh, and may be sent a great distance by inserting their ends in water or moist moss; though, in general, they should be used as soon after gathering as possible; indeed, as in grafting and inarching, the whole operation ought to be performed with the greatest celerity.

2056. Kinds of budding. Professor Thouin enumerates twenty-three species and varieties of budding; but we shall here describe only four, of which but one variety is in general use in Britain.

2057. Shield-budding, or T budding (fig. 382.) is thus performed: — Fix on a smooth part on the side of the stock, rather from than towards the sun, and of a height depending, as in grafting, on whether dwarf, half, or whole standard-trees are desired; then, with the budding-knife, make a horizontal cut across the rind, quite through to the firm wood; from the middle of this transverse cut, make a slit downward, perpendicularly, an inch or more long, going also quite through to the wood. This done, proceed with all expedition to take off a bud; holding the cutting, or scion, in one hand, with the thickest end outward, and with the knife in the other hand, enter it about half an inch or more below a bud, cutting near half way into the wood of the shoot, continuing it with one clean slanting cut, about half an inch or more above the bud, so deep as to take off part of the wood along with it, the whole about an inch and a half long (fig. 382. a); then directly with the thumb and finger, or point of the knife, slip off the woody part remaining to the bud; which done, observe whether the eye or gum of the bud remains perfect; if not, and a little hole appears in that part, it is improper, or as gardeners express it, the bud has lost its root, and another must be prepared. This done, placing the back part of the bud or shield between your lips, expeditiously with the flat haft of the knife separate the bark of the stock on each side of the perpendicular cut, clear to the wood (c), for the admission of the bud, which directly slip down, close between the wood and bark, to the bottom of the slit (d). The next operation is to cut off the top part of the shield (b) even with the horizontal first made cut, in order to let it completely into its place, and to join exactly the upper edge of the shield with the transverse cut, that the descending sap may immediately enter the bark of the shield, and protrude granulated matter between it and the wood, so as to effect a living union. The parts are now to be immediately bound round with a ligament of fresh bass (e), previously soaked in water, to render it pliable and tough, beginning a little below the bottom of the perpendicular slit, proceeding upward closely round every part, except just over the eye of the bud, and continue it a little above the horizontal cut, not too tight, but just sufficient to keep the whole close, and exclude the air, sun, and wet.
2058. **Shield-budding reversed, or reversed T budding** differs from the former in having the transverse cut made at the bottom of the perpendicular slit, instead of at its top, and of course the shield is reversed in its position. This mode is represented as preferable to the other by such as contend that the sap rises in the bark equally with the wood; but as this opinion is now generally considered as exploded, the first, or T mode, may justly be considered as the most scientific mode of budding. Professor Thouin describes shield-budding reversed under the name of *Schmerwoueth*. The advantages attending it, he says, are, that it is not easily drowned with sap or gum; and the disadvantages, that it often fails when there is a scarcity of sap. It is practised occasionally in the orange-nurseries near Genoa, as may be seen in the plants imported to this country.

2059. **Scalope-budding** consists in paring a thin tongue-shaped section of bark from the side of the stock; and in taking a similar section from the shoot of buds, in neither case removing the wood. The section or shield containing the bud is then laid on the corresponding scallop in the stock; its upper edge exactly fitted, as in shield-budding, and at least one of its edges, as in whip-grafting. After this, it is tied in the usual way. The advantages of this mode are, that it can be performed when the wood and bark do not separate freely; on trees having very stiff, thick, suberose barks, and at any season of the year. Its disadvantages are, that it requires longer time to perform the operation, and is less certain of success. The French gardeners often bud their roses in this manner in spring; and if they fail, they have a second chance in July by using the common mode.

2060. **Budding with double ligatures** is a mode invented by Knight, and described by him (*Hort. Trans.* vol. i. 194.) as "a new and expeditious mode of budding." The operations are performed in the manner first above described; but instead of one ligature, two are applied, one above the bud inserted upon the transverse section through the bark; the other, which had no farther office than that of securing the bud, was applied below in the usual way. As soon as the buds had attached themselves, the lower ligatures were taken off; but the others were suffered to remain. "The passage of the sap upwards was in consequence much obstructed, and the inserted buds began to vegetate strongly in July (being inserted in June); and when these had afforded shoots about four inches long, the remaining ligatures were taken off; to permit the excess of sap to pass on; and the young shoots were nailed to the wall. Being there properly exposed to light, their wood ripened well, and afforded blossoms in the succeeding spring; and these would," he adds, "no doubt, have afforded fruit; but that, leaving my residence, I removed my trees," &c.

2061. **Future treatment.** In a fortnight at farthest after budding, such as have adhered may be known by their fresh appearance at the eye; and in three weeks all those which have succeeded will be firmly united with the stock, and the parts being somewhat swelled in most species, the bandage must be loosened, and a week or two afterwards finally removed. The shield and bud now swell in common with the other parts of the stock; and nothing more requires to be done till spring, when, just before the rising of the sap, they are to be headed down close to the bud, by an oblique cut, terminating about an eighth or a quarter of an inch above the shield. In some cases, however, as in grafting, a few inches of the stalk is left for the first season, and the young shoot tied to it for protection from the winds.

2062. The instruments and materials for budding are merely the budding-knife (fig. 110.) and bass ligatures.

**Subsect. 6. Propagation by Cuttings.**

2063. **Propagation by cuttings** has been long known, and is abundantly simple when applied to such free-growing hardy shrubs, as the willow (fig. 383. a) or the gooseberry (b); but considered as the chief mode of propagating most of the ericeae, myrteae, pro-

![Image of budding](image-url)

teaceae, &c. becomes one of the most delicate and difficult modes of continuing the species, and fifty years ago was an operation known to very few of even the first-rate gardeners. It may be considered, as to the choice of cuttings, their preparation, their insertion in the soil, and their future management.
2064. In respect to the choice of cuttings, those branches of trees and shrubs which are thrown out nearest the ground, and especially such as recline, or nearly so, on the earth's surface, have always the most tendency to produce roots. Even the branches of resinous trees, which are extremely difficult to propagate by cuttings, when reclining on the ground, if accidentally, or otherwise, covered with earth in any part, will there often throw out roots, and the extremity of the lateral shoot will assume the character of a main stem, as may be sometimes seen in the larch, spruce, and silver fir. Cuttings then are to be chosen from the side shoots of plants, rather than from their summits or main stems; and the strength and health of side shoots being equal, those nearest the ground should be preferred. The proper time for taking cuttings from the mother plant is when the sap is in full motion, in order that, in returning by the bark, it may form a callus or protruding ring of granular substance, between the bark and wood whence the roots proceed. As this callus, or ring of spongy matter, is generally best formed in ripened wood, the cutting, when taken from the mother plant, should contain a part of the former year, or in plants which grow twice a year, of the wood of the former growth; or in the case of plants which are continually growing, as most evergreen exotics, such wood as has begun to ripen, or assume a brownish color. This is the true principle of the choice of cuttings as to time; but there are many sorts of trees, as willow, elder, &c. the cuttings of which will grow almost at any season, and even if removed from the mother plant in winter, when the sap is comparatively at rest. In these and other trees, the principle of life seems so strong, and so universally diffused over the vegetable, that very little care is requisite for their propagation. Cuttings from herbaceous plants are chiefly chosen from the low growths, which do not indicate a tendency to blossom; but they will also succeed in many cases, when taken from the flower-stems, and some rare sorts of florists' and border flowers, as the dahlia, rocket, cardinal-flower, scarlet lychmis, wallflower, &c. are so propagated.

2065. The preparation of the cutting depends on, or is guided by this principle, that the power of protruding buds or roots resides chiefly, and in most cases entirely, at what are called joints, or at those parts where leaves or buds already exist. Hence it is that cuttings ought always to be cut across, with the smoothest and soundest section possible, at an eye or joint. And as buds are in a more advanced state in wood somewhat ripened or fully formed, than in a state of formation, this section ought to be made in the wood of the growth of the preceding season; or as it were in the point between the two growths. It is true, that there are many sorts of cuttings, which not only throw out roots from the ring of granulated matter, but also from the sides of every part of the stem inserted in the soil, whether old and large (c), or young and small (d, e), as willows, currants, vines, &c.; but all plants which are difficult to root, as heaths (f), camellias, orange-trees, &c. will be found in the first instance, and for several years after propagation, to throw out roots only, from the ring of herbaceous matter above mentioned; and to facilitate the formation of this ring, by properly preparing the cuttings of even willows and currants, must be an obvious advantage. It is a common practice to cut off the whole or a part of the leaves of cuttings, which is always attended with bad effects in evergreens, in which the leaves may be said to supply nourishment to the cutting till it can sustain itself. This is very obvious in the case of striking from buds (g), which, without a leaf attached, speedily rot and die. Leaves alone, as in bryophyllum calycinum, will even strike root and form plants in some instances; and the same, as Professor Thouin observes, may be stated of certain flowers and fruits.

2066. Cuttings which are difficult to strike may be rendered more tractable by previous ringing; if a ring be made on the shoot which is to furnish the cutting, a callus will be created, which, if inserted in the ground after the cutting is taken off, will freely emit roots. A ligature would perhaps operate in a similar manner, though not so efficiently; it should lightly encircle the shoot destined for a cutting, and the latter should be taken off when an accumulation of sap has apparently been produced. The amputation in the case of the ligature, as well as in that of the ring, must be made below the circles, and the cutting must be so planted as to have the callus covered with earth. (Hort. Trans. vol. iv. 558.)

2067. The insertion of the cuttings may seem an easy matter, and none but a practical cultivator would imagine that there could be any difference in the growth, between cuttings inserted in the middle of a pot, and those inserted at its sides. Yet such is actually the case, and some sorts of trees, as the orange, ceratonia, &c. if inserted in a mere mass of earth, will hardly, if at all, throw out roots, while, if they are inserted in sand, or in earth at the sides of the pots, so as to touch the pot in their whole length, they seldom fail of becoming rooted plants. Knight found the mulberry strike very well by cuttings, when they were so inserted, and when their lower ends touched a stratum of gravel or broken pots; and Hawkins, (Hort. Trans. vol. ii. p. 12.) who had often tried to strike orange-trees, without success, at last heard of a method (long known to nurserymen, but which was re-discovered by Luscombe), by which, at the first trial, eleven cuttings
out of thirteen grew. "The art is, to place them to touch the bottom of the pot; they are then to be plunged in a bark or hot-bed, and kept moist."

2068. The management of cuttings after they are planted, depends on the general principle, that where life is weak, all excesses of exterior agency must have a tendency to render it extinct. No cutting requires to be planted deep, though such as are large \( i \) ought to be inserted deeper than such as are small \( f, h \). In the case of evergreens, the leaves should be kept from touching the soil \( k \) otherwise they will damp or rot off; and in the case of tubular-stalked plants, which are in general not very easily struck, owing to the water lodging in the tube, and rotting the cutting, both ends \( l \) in some cases (as in common honeysuckle,) be advantageously inserted in the soil, and besides a greater certainty of success, two plants will be produced. Too much light, air, water, heat, or cold are alike injurious. To guard against these extremes in tender sorts, the means hitherto devised is that of enclosing an atmosphere over the cuttings, by means of a hand or bell glass, according to their delicacy. This preserves a uniform stillness and moisture of atmosphere. Immersing the pot in earth (if the cuttings are in pots) has a tendency to preserve a steady uniform degree of moisture at the roots; and shading, or planting the cuttings, if in the open air, in a shady situation, prevents the bad effects of excess of light. The only method of regulating the heat is by double or single coverings of glass or mats, or both. A hand-glass placed over a bell-glass will preserve, in a shady situation, a very constant degree of heat. What the degree of heat ought to be, is generally decided by the degree of heat requisite for the mother plant. Whatever degree of heat is natural to the mother plant when in a growing state will, in general, be most favorable to the growth of the cuttings. There are, however, some variations, amounting nearly, but not quite, to exceptions. Most species of the erica, dahlia, and geranium strike better when supplied with rather more heat than is requisite for the growth of these plants in green-houses. The myrtle tribe and camellias require rather less; and in general it may be observed, that to give a lesser portion of heat, and of every thing else proper for plants in their rooted and growing state, is the safest conduct in respect to cuttings of ligneous plants. Cuttings of deciduous hardy trees taken off in autumn should not, of course, be put into heat till spring, but should be kept dormant, like the mother tree. Cuttings of succulents like geraniums will do well both with ordinary and extraordinary heat.

2069. Piping is a mode of propagation by cuttings, and is adopted with herbaceous plants having jointed tubular stems, as the calluna tribe; and several of the grasses, and tree arundins, might be propagated in this manner. When the shoot has nearly done growing, which generally happens after the blossom has expanded, its extremity is to be separated at a part of the stem where it is nearly, or at least somewhat indurated or ripened. This separation is effected by holding the root end between the finger and thumb of one hand, below a pair of leaves, and with the other, pulling the top part above the pair of leaves, so as to separate it from the root part of the stem at the socket formed by the axilie of the leaves, leaving the stem to remain with a tubular or pipe-looking termination. These pippings, or separated parts \( k \), are inserted without any further preparation in finely sifted earth, to the depth of the first joint or pipe, gently firm it with a small dibber, watered, a hand-glass placed over them, and their future management regulated on the same general principles as that of cuttings.

Sect. III. Operations of Rearing and Culture.

2070. Operations of rearing and cultivation are various, and some of them of the simplest kind, as stirring the soil, cutting, sawing, weeding, &c. have been already considered as garden-labors on the soil and on plants (1862. & 1882.) ; we here, therefore, confine ourselves to the more complex processes of sowing, planting, watering, transplanting, pruning, thinning, training, and blanching.

Subsect. I. Sowing, Planting, and Watering.

2071. Sowing is the first operation of rearing. Where seeds are deposited singly, as in rows of beans or large nuts, they are said to be planted; where dropt in numbers together, to be sown. The operation of sowing is either performed in drills, patches, or broad-cast. Do drills are small excavations formed with the draw-hoe, generally in straight lines parallel to each other, and in depth and distance apart varying according to the size of the seeds and future plants. In these drills, the seeds are strewn from the hand of the operator, who, taking a small quantity in the palm of his hand and fingers, regulates its emission by the thumb. Some seeds are very thinly sown, as the pea and spinach; others thick, as the cress and small salading. For sowing by bedding-in, see Bedding-in planting, (2091.), and Cuffing, (1875.)

2072. Patches are small circular excavations made with the trowel; in these, seeds are either sown or planted, thicker or thinner, and covered more or less, according to D d
their natures. This is the mode adopted in sowing in pots, and generally in flower-borders.

2073. In **broad-cast sowing**, the operator scatters the seed over a considerable breadth of surface previously prepared by digging or otherwise minutely pulverised. The seed is taken up in portions in the hand, and dispersed by a horizontal movement of the arm, to the extent of a semicircle, opening the hand at the same time, and scattering the seeds in the air, so as they may fall as equally as possible over the breadth taken in by the sower at once, and which is generally six feet; that being the diameter of the circle in which his hand moves through half the circumference. In sowing broad-cast on the surface of beds, and in narrow strips or borders, the seeds are dispersed between the thumb and fingers by horizontal movements of the hand in segments of smaller circles.

2074. **Dry weather is essentially requisite for sowing**, and more especially for the operation of covering the seed, which in broad-cast sowing is done by treading or gently rolling the surface and then raking it; and in drill-sowing, by treading in the larger seeds, as peas, and covering with the rake; smaller seeds, sown in drills, are covered with the same implement without treading.

2075. **Planting, as applied to seeds, or seed-like roots, as potatoes, bulbs, &c.** is most frequently performed in drills, or in separate holes made with the dibber; in these, the seed or bulb is dropped from the hand, and covered with or without treading, according to its nature. Sometimes planting is performed in patches, as in pots or borders, in which case the trowel is the chief implement used.

2076. **Quincunx** is a mode of planting in rows, by which the plants in the one row are always opposed to the blanks in the other, so that when a plot of ground is planted in this way, the plants appear in rows in four directions.

2077. **Planting, as applied to plants already originated**, consists generally in inserting them in the soil of the same depth, and in the same position as they were before removal, but with various exceptions. The principal object is to preserve the fibrous roots entire, to distribute them equally around the stem among the mould or finer soil, and to preserve the plant upright. The plant should not be planted deeper than it stood in the soil before removal, and commonly the same side should be kept towards the sun. Planting should, as much as possible, be accompanied by abundant watering, in order to consolidate the soil about the roots; and where the soil is dry, or not a stiff clay, it may be performed in the beginning of wet weather in gardens; and in forest-planting, on dry soils, in all open weather during autumn, winter, and spring.

2078. **Watering** becomes requisite in gardens for various purposes, as aliment to plants in a growing state, as support to newly transplanted plants, for keeping under insects, and keeping clean the leaves of vegetables. One general rule must be ever kept in mind during the employment of water in a garden; that is, never to water the top or leaves of a plant when the sun shines. A moment’s reflection will convince any one that this rule is agreeable to the laws of nature, for during rain the sun’s rays are intercepted by a panoply of fog or clouds. All watering, therefore, should be carried on in the evening or early in the morning, unless it be confined to watering the roots, in which case, transplanted plants, and others in a growing state, may be watered at any time; and if they are shaded from the sun, they may also be watered over their tops. Watering over the tops is performed with the rose, or dispenser attached to the spout of the watering-pot, or by the syringe or engine. Watering the roots is best done with the rose; but in the case of watering pots in haste, and where the earth is hardened, it is done with the naked spout. The compartments of gardens are sometimes watered by a leather tube and muzzle attached at pleasure to different pipes of supply; but this depends on local circumstances, and, in general, it may be observed that the great increase of labor occasioned by watering compartments renders the practice very limited. In new-laid turf, or lawns of a loose porous soil and too mossy surface, the water-barrel (fig. 205.) may be advantageously used.

**Subsect. 2. Transplanting.**

2079. **Transplanting** is the next operation of rearing, and consists in removing propagated plants, whether from seeds, cuttings, or grafts, according to their kinds and other circumstances, to a situation prepared to receive them. The uses of transplanting ligneous plants are chiefly to increase the number of fibrous roots, so as to prepare or fit young subjects for successful removal from the places where they are originated to their final destination; but in herbaceous vegetables it is partly used to increase the proportion of fibrous roots in plants, relatively to their ramose roots, by which it is found the size and succulence of their leaves, flowers, and fruit are increased. Transplanting involves three things: first, the preparation of the soil to which the plant is to be removed; secondly, the removal of the plant; and, thirdly, the insertion in the prepared soil.
The preparation of the soil implies, in all cases, stirring, loosening, mixing, and commination; and, in many cases, the addition of manure or compost, according to the nature of the soil and plant to be inserted, and according as the same may be in the open ground, or in pots or hot-houses.

The removal of the plant is generally effected by loosening the earth around it, and then drawing it out of the soil with the hand; in all cases avoiding as much as possible to break, or bruise, or otherwise injure the roots.

In the case of small seedling plants, merely inserting the spade and raising the portion of earth in which they grow will suffice; but in removing larger plants, it is necessary to dig a trench round, or on one side of the plant. In some cases, the plant may be lifted with a ball or mass of earth, containing all or great part of its roots, by means of the trowel or transplanter (Fig. 93.); and in others, as in the case of large shrubs or trees, it may be necessary to cut the roots at a certain distance from the plant, one year before removal, in order to furnish them with young fibres, to enable them to support the change. In pots, less care is necessary, as the roots and ball of earth containing them are, or may be, preserved entire.

Inserting the removed plant in the prepared soil, is performed by making an excavation suitable to the size of the plant, with the dibber, trowel, or spade, placing the plant in it to the same depth as before its removal, and then covering its roots with earth firmly, but not harshly or indiscriminately, pressed to it; lastly, adding water. There are various modes of insertion according to the age and kind of plant, tools employed, object in view, &c. of which the following are the principal species and varieties.

Of spade planting there are a variety of different sorts, known by the names of hole planting, trench planting, trenching-in planting, slit or crevice planting, boling-in planting, drill planting, bedding-in planting, furrow planting, &c. All these modes are almost peculiar to nursery gardening.

Hole planting is the principal method practised in the final planting of all sorts of trees and shrubs in the open ground; and is performed by making round holes for the reception of each plant somewhat larger than its roots, then inserting the plant according to the general principles of planting.

Trench planting is practised in nurseries, in planting out seedlings of trees, and plants in rows, also for bedding-in shrubs, small herbs, and flowers. It is performed by opening a long narrow trench with a spade, making one side upright, placing the plants against the upright side, and turning in the earth upon their roots.

Trenching-in planting is practised in light pliable-working ground, for planting young trees in nurseries, and hedges, &c. It is performed by digging a trench one spade wide, by a line, and planting from one end of the trench towards the other, as the trench is being dug. Thus, the line being set and the plants ready, with your spade begin at one end, and standing sideways to the line, throw out a spadeful of earth for each plant, making a small aperture, another person being ready with the plants, let him directly insert one in the opening, whilst the digger proceeds with the digging, and covers the roots of the plants with the earth of the next spit. Another aperture being thereby also formed, place therein another plant, and so on.

Another method of trenching-in planting sometimes used for planting certain roots, such as horse-radish-sets, potatoes, &c. is performed by common trenching, placing a row of sets in each trench or furrow. The horse-radish should be planted in the bottom of the open trench, if not above twelve inches deep, turning the earth of the next over them; and the potato-sets placed about four or six inches deep, and cover them also with the earth of the next trench.

Slit planting. This method is performed by making slits or crevices with a spade in the ground, at particular distances, for the reception of small trees and shrub-plants. It is practised sometimes in the nursery, in putting out small trees, suckers, &c. from about a foot or eighteen inches or two feet high, and that have but small roots; it is also sometimes practised where very large tracts of forest-trees are to be planted in the cheapest and easiest mode of performance; the following is the method:—A line is set or a mark made accordingly; then having a quantity of plants ready, for they must be planted as you proceed in making the slits, let a man, having a good clean spade, strike it into the ground with its back close to the line or mark, taking it out again directly, so as to leave the slit open: he then gives another stroke at right angles with the first: then the person with the plants inserts one immediately into the second-made crevice, bringing it up to the line or mark, and directly pressing the earth close to the plant with his foot; proceed in the same manner to insert another plant, and so on. A man and a boy, by this method, will plant ten or fifteen hundred, or more, in a day.

Holing-in planting. This is sometimes used in the nursery in light loose ground, and sometimes in planting potatoes, &c. in pliable soils. The ground being previously dug or trenched, and the spade kept sharp, with his spade, take out a small slit of earth, and in the hole so formed let another person directly deposit a plant; then let the digger take another spadeful of earth, and turn the earth thereof into the first hole over the roots; then placing directly another plant in this second opening, let the digger cover it with the earth of a third, and so on.

Drill planting. This is by drawing drills with a hoe, from two to four or five inches deep, for the reception of seeds and roots, and is a commodious method of planting many sorts of large seeds, such as walnuts, chestnuts, &c.; sometimes also broad beans, but always kidneybeans and peas; likewise of planting many sorts of bulbous roots, when to be deposited in beds by themselves. The drills for all of these purposes should be drawn with a common hoe, two or three inches deep, though, for large kinds of bulbous roots, four or five inches deep will be requisite, and the seeds and roots should always be covered the depth of the drills.

Bedding-in planting. This is frequently practised for planting the choicer kinds of flowering buds, such as hyacinths, &c.; also for larger seeds of trees; as acorns, large nuts, and other kinds of seeds, stones, and kernels, and is performed by drawing the earth from off the tops of the beds, some inches in depth, in the manner of cufifying, then planting the seeds or roots, and covering them over with the earth, drawn off for that purpose.

Dd 2
The following is the mode of performance: — The ground must be previously digged or trench'd, raked, and formed into beds three or four feet wide, with alleys between bed and bed; then with a rake or spade, trim the earth evenly from off the top of the bed into the alleys, from two or three to four inches deep for bulbous roots, and for seeds, one or two inches, according to what they are, and their size; then, if for bulbous roots, draw lines along the surface of the bed, nine inches' distance, and place the roots, bottom downward, along the lines, six or eight inches apart, thrusting the bottom into the earth. Having thus planted one bed, then with the spade, let the earth that was drawn off into the alley be spread evenly upon the bed again, over the roots or seeds, being careful that they are covered all equally of the above depth, and rake the surface smooth. This method is also practised in nurseries, for sowing such seeds as require great accuracy in covering, as the larch, pine, and fir tribes; and, indeed, for most other tree-seeds.

2092. Furrow planting. This is by drawing furrows with a plough, and depositing sets or plants in the furrow, covering them in also with the plough. It is sometimes practised for planting potatoe-sets in fields, and has been practised in planting young trees, for large tracts of forest-tree plantations, where the cheapest and most expeditious method was required; but it can only be practised advantageously in light pliable ground. It is thus performed: a furrow being drawn, one or two persons are employed in placing the sets or plants in the furrow, whilst the plough following immediately with another furrow, turns the earth thereof in upon the roots of the plants.

2093. Dibble planting. This is the most commodious method for planting most sorts of fibrous-rooted seedling plants, slips, off-sets, and cuttings both of herbaceous and shrubby kinds; and likewise for some kinds of seeds and roots, such as broad beans, potatoe-sets, Jerusalem artichokes, and horseradish-sets, bulbous roots, &c. It is expeditiously performed with a dibble or setting-stick; therewith making a narrow hole in the earth for each plant or root, inserting one in each hole as you go on, &c.

2094. Trowel planting. This is performed with a garden-trowel, which being made hollow like a scoop, is useful in transplanting many sorts of young fibrous-rooted plants with balls of earth about their roots, so as they may not be checked by their removal.

2095. Planting with balls. By removing a plant with its roots firmly attached to a surrounding ball of earth, it continues in a growing state, without receiving any, or but very little check from its removal. This mode is often practised, more particularly with the more delicate and chooser kinds of exotics, both trees, shrubs, and herbaceous plants; and occasionally to many of the fibrous-rooted flowery plants, both annuals and perennials, even in their advanced growth and flowering state, when particularly wanted to supply any deficient compartments, or when intended to remove any sort of tree or plant out of the proper planting season, as very late in spring, or in summer. The most difficult tribe of plants to transplant, when in a growing state, are bulbous roots; which succeed with difficulty, even when removed with balls attached.

2096. Planting by muddling-in (enschlaman) is a German practice in planting fruit-trees, particularly suitable to the dry sandy soils of that country, and sometimes adopted in similar situations in this country. The pit being dug out, the mould in its bottom is watered and stirred so as to form a mass of mud about half the depth of the pit; the tree is then inserted, and its roots worked up and down in the mud so as to spread them as much as possible equally through it. More mud, previously prepared, is poured in till the pit is full, which is then covered with dry earth, raised round the stem, but hollowed in the middle, so as to form a basin round its stem, and finally covered with litter (mulched), and, if a standard, is fastened to a stake to protect it from winds. Diel, a scientific German author already mentioned (224.), assures his readers, that trees planted in this way in spring thrive better in cold situations than those planted in the ordinary way in the preceding autumn; and, that though it occasions considerable trouble, it should never be neglected either in spring or autumn. 'He found it also particularly useful in the case of planting fruit-trees in pots. (Obst. Orangerie, &c. vol. ii.) Pontey, alluding to this mode, says "planting in a puddle occasions the soil speedily to firm, not only too hard for the roots of the plant to spread, but also so far as perfectly to exclude water." (Rural Improver, p. 89.)

2097. Planting by fixing with water is an excellent variety of the last species. It has been successfully practised by Pontey, and is thus described by him: — The hole being made, and the tree placed in it in the usual manner, the root is then slightly covered with the finer part of the soil; the tree being at the same time shaken, as is common, to settle the earth among its roots. Water is then applied by a common garden watering-pot, by pouring it upon the soil with some force, in order to wash it close to, and among the roots of the plant. But this can only be done effectually by elevating the pot as high in the hands as can be conveniently used, after first taking off the rose. It will be obvious, that for such purposes a large pan with a wide spout is to be preferred. The hole is then filled up with the remainder of the soil, and that again consolidated with water as before, which usually finishes the business. The foot is never applied except in
the case of bad roots, which sometimes occasion the plants to be left a little leaning. In such cases, the application of the foot slightly, once or twice, after the soil has become somewhat firm (which generally happens in less than an hour), sets the tree upright, and so firm as to require no staking. (Rural Improver, p. 89.)

2098. **Panning, mulching, and staking.** Panning is an almost obsolete phrase, applied by Switzer, and writers of his day, to the operation of forming a hollow or basin round trees, for the purpose of retaining water when given them by art. Mulching consists in laying a circle of litter round the roots of newly planted trees, to retain the natural humidity of the soil, or to prevent the evaporation of artificial watering. **Staking** is the operation of supporting standard-trees, by tying them with straw, or other soft ties, to poles or stakes inserted firmly in the ground close to the tree.

2099. **Planting edgings.** Edgings are rows of low-growing plants, as box, daisy, &c. planted in lines along the margins of walks and alleys, to separate them from the earth and gravel. They should always be planted before either the gravel or substratum are deposited. To perform the operation, the first thing is to form the surfaces for the edgings in planes corresponding with the established slopes or levels of the borders or other parts of the garden, observing, that a line crossing the walk at right angles, and touching both of the prepared surfaces, must always be a horizontal line, whether the walk be on a level or slope. Suppose a walk 150 feet long on a gentle declivity, and that the level or height of both ends are fixed on; then by the operation of the browning-pieces, any number of intermediate points is readily formed to the same slope, and the spaces between these points are regulated by the eye or the application of the straight-edge. The earth, so formed into a regular slope, need not exceed about a foot in breadth, on which the line being stretched, half is to be cut down, with a face sloping towards the walk, and against this sloping, or nearly perpendicular face, the box is to be laid as thin and regular as practicable, and every where to the same height, say one inch above the soil. The box is to be previously prepared by separation, and shortening the roots and tops. This is one of those operations, on the performance of which, with accuracy, depends much of the beauty of kitchen-gardens.

2100. **Planting verges.** Verges are edgings of turf, generally two feet broad or upwards. The turves being cut in regular laminae, with the edges or sides of each turf perpendicular, and the two ends oblique in the same slope, they are to be placed so as the one may fit exactly to the other. They are next to be beat with the beetle, afterwards watered, and again beat or rolled, and finally a line applied to their edges, and the *raser* (fig. 101.) used to cut them off neatly and perpendicularly. If the turf is from loamy soil, this is readily effected; but if no turf can be got but from sandy soils, then it must be cut very thin, and placed on good earth or loam, according to circumstances. Verges are sometimes, though rarely, formed of chamomile, strawberries, dwarf-thyme, &c. in which situations the wood-strawberry and chamomile produce abundant crops.

2101. **Transplanting or laying down turf.** Turfing, as this operation is commonly called, consists in laying down turf on surfaces intended for lawn, in parterres or pleasure-grounds. The turf is cut from a smooth firm part of an old sheep-pasture, free from coarse grasses, in performing which the ground is first crossed by parallel lines, about a foot asunder, and afterwards intersected by others three feet asunder, both made with a line and the turf-raser. Afterwards, the turf-spade or turfing-iron is employed to separate the individual turves, which are rolled up, and conveyed to the spot where they are to be used. It is to be observed, that, in this case, all the sides of each turf are bevelled; by which means, when they are laid down exactly as they were before being taken up, their edges will fit, and in some degree lap over each other, and thereby, after rolling, a more compact surface will be formed. The surface on which the turves are to be laid, ought previously to be either dug or trenched, so as to be brought to one degree of consistency, and then rolled, so as it may not afterwards sink; the turves being laid so as to fit, are to be first beaten individually, and then watered and rolled till the whole is smooth and even.

2102. **In transplanting in pots,** the general practice is to begin with the smallest-sized pot, and gradually to transplant into others larger, as the plant advances, and as the object may be to produce a large or a small plant. In the case of balsams and tender annuals, this may require to be performed three or four times a month, till the plant has attained its full size; in the case of heaths, not more than once a year or seldom.

2103. **The operation of potting** is thus performed. Having the pots and mould ready for the reception of the intended plants, observe, previous to planting them, to place some pieces of tile, potsherds, or oyster-shells, or gravel over the hole at the bottom of the pot, both to prevent the hole from being clogged and stopped with the earth, and the earth from being washed out with occasional watering; and also to prevent the roots of the plants from getting out. Having secured the holes, place some earth in the bottom of each pot, from two or three to six or inches more in depth, according to the size of the pot, and the roots of the plant. This done, insert the plant in the middle of the pot, upon the earth, in an upright position; if without a ball of earth, spread its roots equally every way, and directly add a quantity of fine mould about all the roots and fibres, shaking the pot to cause the earth to settle close about them; at the same time, if the roots stand too low, shake it gently up, as you shall see occasion; and having filled the
pot with earth, press it gently all round with the hand to settle it moderately firm in every part, and to steady the upright posture of the plant, raising the earth, however, within about half an inch, or less, or the plant will be likely to lean. If the plant is a shrub, and there is a risk of receiving occasional waterings. As soon as the plant is thus potted, give directly a moderate watering to settle the earth more effectually close about all the roots, and promote their shooting into the new earth; repeating the waterings as occasion requires.

2104. Transplanting potted plants from one pot to another is called shifting; and is performed with the whole ball of earth contained in the pot entire, so as to preserve the plant in its growing state.

2105. The method of removing them out of the pots with balls is generally easily effected. Sometimes in small plants it is performed by turning the pot upside down, and striking the edge against the side of a bench, or placing it horizontally on a wheeled instrument of the like, with a side, or occasionally with a board that is very well rooted, and whose numerous fibres surround the outside of the ball, will readily quit the pot by drawing it by the stem. But if, by either of the above methods, the ball will not readily quit the pot, thrust a narrow thin slip of wood down, of wood the ball will come out. Sometimes, however, the bellied form of the pot, and the luxuriance of the roots which circulate between the pot and earth, pre- vent the possibility of removing the ball entire; in which case, either that circumstance must be dispensed with, or the pot broken.

2106. In replanting in larger pots, the first step regards the management of the numerous fibres which surround the outside ball. When these are not numerous, the general practice is to leave them untouched; but when they are so abundant as to form a sort of matted coat, like the inside of a bird's nest all around, then the practice is to trim the greater part of them off close to the ball, both on the sides and bottom, together with some of the outward old earth of the ball; then having the pots of proper sizes, larger than the former ones, and having secured the holes at bottom, and put in some fresh compost, deposit the plant with its entire ball in the pot, taking care that it stands erect, and if the same depth as before; and if not, fill around the ball with fresh mould, and ram it down with a broad stick, round the sides with a broad stick, adding more mould gradually, and raising it so as to cover the old ball, and finish with a moderate watering, to settle the new earth close in every part. Hayward has suggested the idea of a movable bed, for more readily shifting potted plants with naturally roots; and we have already (1412) described the orange-boxes used at Versailles, and by Mean at Wormsleybury, in which fresh earth can be put to the sides of the largest plants with little trouble.

2107. In transplanting with balls is to be avoided in the case of diseased plants, unless it be evident that the disease is in connection with the ball of earth and the roots. Very frequently, however, the diseases of plants in pots arise from the want of a proper vent for the water, and from their having had too much given them; hence in transplanting such plants, it is eligible to shake the whole entirely out of the earth, in order to examine its roots, and trim off all decayed and other bad parts; then having a fresh pot, and some entire new compost, replant it carefully and directly.

2108. In potting plants from the open ground, or beds of earth on dung, or otherwise, if they have been previously pricked out at certain distances, and have stood long enough to fix their roots firmly, they may be pricked to pots with balls, by the proper use of the trowel, transplanter, or hollow spade. Sometimes, however, cannot often be raised with balls, and are therefore planted in the smallest-sized pots first, and some entire removed into larger ones with their balls entire.

2109. Plants in pots are never shifted directly from small into large pots, but always into a size only one greater, in order that in which they are. Experience proves that this is the best mode, and that plants, in general, thrive best in small pots. The reason seems to be that, in large pots, the roots are apt to be chilled and rotted by the retention of more water than is requisite for their wellbeing.

SUBSEC. 3: Pruning.

2110. The amputation of part of a plant with the knife, or other instrument, is practised for various purposes, but chiefly on trees, and more especially on those of the fruit-bearing kind. Of two adjoining and equal-sized branches of the same tree, if the one be cut off, that remaining will profit by the sap which would have nourished the other, and both the leaves and the fruits which it may produce will exceed their natural size. If part of a branch be cut off which would have carried a number of fruits, those which remain will set, or fix better, and become larger. On the observation of these facts is founded the whole theory of pruning; which, though like many other operations of art, cannot be said to exist very obviously in nature, is yet the most essential of all operations for the culture of fruit-trees.

2111. The objects of pruning may be reduced to the following: promoting growth and bulk; lessening bulk; modifying form; promoting the formation of blossom-buds; enlarging fruit; adjusting the stem and branches to the roots; renewal of decayed plants or trees; and removal or cure of diseases.

2112. In promoting growth and bulk, pruning is the simplest object of pruning, and is chiefly that which is employed by nursery-men with young trees of every description. The art is to cut off all the weak lateral shoots, that the portion of sap destined for their nourishment may be thrown into the main shoots; and this is done by the simple case of cutting off the shoots, in order to produce three or four shoots instead of one. In general, more bulk being the object, upward shoots are encouraged rather than lateral ones; excepting in the case of trained trees, where shoots are encouraged at all angles, from the horizontal to the perpendicular, but more especially at the medium of 45 degrees. In old trees, this object is greatly promoted by the removal, with the proper instruments, of the dead or already scaling off outer bark.

2113. Pruning for lessening the bulk of the tree is also chiefly confined to nursery-practice, as necessary to keep un-sized trees of a portable size. It consists in little more than what is technically called scarring the plant. That is to say, cutting off the outer shoots which are too large. In some cases, some of the lower lateral shoots. Care is taken to cut to a leaf-bud (1885), and to choose such from among the side, upper, or under buds of the shoot according as the succeeding year's shoots may be to be directed. Apart from the trials of some of the fruit, or in the case of trees, it is evident that this unnatural operation persisted in for a few years must render the tree knotty and unsightly, and in stone-fruits, at least, it is apt to generate canker and gum.

2114. Pruning for modifying the form of the tree embraces the management of the plant from the time of its planting. Almost every tree has a different natural habit of growth; and in botanic culture, gardening it is seldom desirable to attempt altering these by pruning, or by any other operation. But in rearing trees planted for timber, it is desirable to throw them as much as possible, into long compact masses; and hence pruning is employed to remove the side branches, and encourage the growth of the bole or stem. Where this operation is begun when the trees are young, it is easily performed every two or three years, and the progress of the tree under it is most satisfactory; when, however, it is
2115. **Pruning fruit-trees.** The grand art of pruning, not only as to the modification of form, but in all its other varieties, relates to fruit-trees, of which the leading characters are standards and wall-trees; the former including dwarfs and half-standards, and the latter, dwarfs and riders.

2116. **In pruning to form standards (arbres à plein-vent, Fr.),** the first thing to be determined on after the plant has been received from the nursery and planted, is, whether the stem is to be tall (haut-tige) or short (basse-tige); and the next, if the head is to be trained in any particular form, as a cone, globe, semi-globe, radiated pyramid, &c.; or left to assume its natural shape. If a cone or pyramid is determined on, then a leading upright shoot must be carefully preserved, and the side shoots kept at regular distances from each other, and as far as practicable, equally extended on the one side of the main stem as on the other, keeping always in view the ultimate figure. If a globe is to be produced no shoot must be permitted to take the lead, but a number encouraged to radiate upwards from the graft, and these kept as regular as possible, both in regard to distance from each other, and of their extremities from the centre of the globe. If the tree is to be left to its natural shape, which in our opinion is by far the best mode, it will, in the apple, pear, cherry, and most other fruit-trees, assume something of the conical shape, at least for some years; but whatever shape it has a tendency to assume, that shape must not be counteracted by the pruner, whose operations must be chiefly negative, or directed to thinning out weak and crowded shoots, and preserving an equal volume of branches on one side of the tree as on the other: in technical language, preserving its balance. Knight's directions for this mode of pruning, both in his Treatise on the Apple and Pear, and in different papers in the Horticultural Transactions, are particularly valuable. For the apple and all standard trees he recommends that the points of the external branches should be every where rendered thin and pervious to the light; so that the internal parts of the tree may not be wholly shaded by the external parts: the light should penetrate deeply into the tree on every side; but not any where through it. When the pruner has judiciously executed his work, every part of the tree, internal as well as external, will be productive of fruit; and the internal part, in unfavorable seasons, will rather receive protection than injury from the external. A tree thus pruned, will not only produce much more fruit, but will also be able to support a much heavier load of it, without danger of being broken; for any given weight will depress the branch, not simply in proportion to its quantity, but in the compound proportion of its quantity and of its horizontal distance from the point of suspension, by a mode of action similar to that of the weight on the beam of the steelyard; and hence a hundred and fifty pounds, suspended at one foot distance from the trunk, will depress the branch which supports it no more than ten pounds at fifteen feet distance would do. Every tree will, therefore, support a larger weight of fruit without danger of being broken, in proportion as the parts of such weight are made to approach nearer to its centre. Hitt recommends that the shape or figure of standards should be conical, like the natural growth of the fir-tree: and this form, or the pyramidal or sub-cylindrical (en querouille, Fr.) is decidedly preferred by the French, and universally employed both by them and the Dutch.

2117. **In pruning to form dwarf-standards (basse-tiges, Fr.),** the plants being received from the nursery, furnished with shoots of one year's growth, are to be cut down to three or four buds, which buds will throw out other shoots the following year, to form the bush or dwarf. If these buds throw out, during the second year, more than can grow the third year without crossing or intermixing with each other, then the superfluous shoots must be cut off; but if too few to form a head regularly balanced, or projecting equally beyond the stem on all sides, then one or more of the shoots in the deficient part must be cut down to three or four eyes, as before, to fill up by shoots of the third year the vacancies in the bush. In this way must the tree be treated year after year, cutting away all cross-placed branches and crowded shoots, till at last it shall have formed a head or bush globular, oblong, or of any other shape, according to its nature, and with this property common to every form, that all the shoots be so far distant from each other as not to exclude the sun's rays, air, or rain, from the blossoms and fruit. Such is the most approved modern mode of training fruit-tree bushes or dwarf-standards; but,
about a century ago, when dwarfs were in the greatest vogue, they were trained into regular geometrical shapes, without the least regard to the natural shape or tendency of the branches of the tree. In the works of Quintiney and Arnaud d’Andilly are described concave, conical, fusiform, spiral, and other dwarfs.

2118. Concave or cup-shaped dwarfs (arboijn boomen, Dut.; en gobelet or en tonnoir, Fr.), being trained concave or hollow in the middle, having all the branches ranged circularly around the stem, in an ascending direction, so as to form the heart of the tree hollow or concave.

2119. Conical or pyramidal dwarfs, tapering like a cone or pyramid from the base to the summit. When pyramidal trees are so pruned that the horizontal branches form stages above one another, they are termed chandelier-like, or en girandole.

2120. Fusiform (en quenouille, Fr.) or convex dwarfs, being trained, bellied out, or somewhat spindle-shaped in the middle, or like a full distaff.

2121. Horizontal dwarfs, in which all the branches were trained in a flat position, parallel to the surface of the earth.

2122. Spiral dwarfs (fig. 384.), in which the branches were trained spirally round stakes, which stakes were afterwards removed.

2123. Fan-dwarfs (palmettes, Fr.) in which the branches were spread out like the hand, or like a spread fan.

2124. Natural dwarfs or bushes (arbres en buisson, Fr.), in which the branches were permitted to advance in their natural mode of growth; being only thinned, or shortened, or deprived of supernumerary side shoots, as already described.

2125. Estimate of the forms of dwarfs. Some authors observe that all these forms may be introduced for the sake of variety; but of all forms which require constraint, as being contrary to the natural shape of the bush and tendency of the branches, it may with certainty be observed, that they can only be maintained by continual exertion in counteracting nature; and that the trees so constrained and cut, generally throw out, at particular parts, such a superfluity of useless wood, as greatly to lessen their tendency to produce blossom-buds. Each variety of the apple-tree, observes Knight, "has its own peculiar form of growth, and this it will ultimately assume, in a considerable degree, in defiance of the art of the pruner." The same remark, it is obvious, applies to every sort of tree.

2126. Pruning half standards is conducted exactly on the same general principles as pruning dwarfs; the only difference between them being that, in the one case, the bush or head is close to the ground, and in the other, it is elevated from it three or four feet. Of the common hardy fruit-trees, it may be observed, that the apple, plum, quince, medlar, and mulberry form a forked irregular head (fig. 385. a), and the pear and cherry a more regular cone or distaff, with lateral branches proceeding from an upright stem (b). The French are particularly expert in pruning their pear-trees into this last form, assisted sometimes by a rod to train the central shoot.

2127. Crown or umbrella headed standards (kroon boomen, Dut.) are a sort of half-standard, formed by the Dutch, and chiefly on dwarfing stocks. The stems are six or seven feet
The trees are apples, six feet high in their stems, from the tops of which, the branches, which are of three or four years' growth, extend outwards, and nearly horizontally in all directions, from five to six feet from the centre. Round the tree, at about three feet from the stem, and at two feet from the ground, is placed a hoop, fastened to stakes, and towards this hoop the ends of the branches are directed by worsted cords fastened to their extremities, and to the hoop. The branches, by this means, assume a curved direction, straighter near to their origin in the centre, much arched afterwards, and having their extremities turned inwards. The average distance from the ground to the ends of the branches thus secured is about four feet. The general outline of the tree has much resemblance to that of a balloon, and the cords which are attached all round to the hoop in a slanting direction inwards, increase the similitude. And once the branches have been thus constrained, the fasteners are removed, and in the winter, these upright shoots which have been made, are shortened to spurs, except where fresh branches are wanted to complete the uniformity and regularity of the whole; and in spring the operation of tying is repeated. It is scarcely possible to conceive a row of trees in a garden more beautiful than one thus arranged, not only from the uniformity in size, and regularity of growth of the trees; but from the beautiful display of blossoms and fruit in the different seasons, occasioned by this peculiar mode of pruning, which is calculated to exhibit the whole so perfectly. The advantages of this method are many and important. The downward inclination given to the branches increases their exposure to form blossom-buds, and consequently to produce more abundantly; the foliage is well exposed to receive the influence of the light and air; the fruit is uniformly distributed over the surface of the tree, and does not suffer from being shaded by irreglarly placed branches; whilst the ligatures at the ends of the shoots keep the whole so steady, that they are never so agitated by wind as to lose their crop prematurely, nor do the branches suffer like those of other trees, by lashing each other in strong gales of wind." (Hort. Trans. vol. v. 186.) However fascinating this plan may appear at first sight, and for a short time, whilst the spurs are short, it is, like most of the French and Dutch modes of training just described, radically bad, and certain of ultimately defeating the object in view. The main effect of trees so constrained will annually be directed to sending up upright shoots from the apex of the balloon; and though these may be "shortened to spurs" for a year or two, the spurs so formed will only bear short shoots on the branches, and these are not of the right size till they are raised, by the means of more spurs, sending up a crowd of shoots, and depriving the pendent branches of nourishment. Every gardener can foresee this. There is only one mode of training that nature approves of, and that is the fan mode. (214.)

2129. Pruning, for the modification of fruit-trees trained on walls (en espalier, Fr.) or on espaliers (en contre-espalier, Fr.), depends on the principle of training which may be adopted. The selection being made of such shoots as are requisite for carrying on the form of the training tree; the others are to be cut off, first on the general principles recommended for all cutting (1884.); and secondly, according to the particular nature of the tree. All trees which are much cut or constrained, have a tendency to throw out over-luxuriant shoots at particular parts of the branches where the sap is suddenly checked; such shoots seem to employ the great body of the sap, and thus divert it from performing its functions in the other parts of the branch or tree. The largest of these shoots, the French term gourmands, or gluttons; and the lesser ones, which have their leaves very distant and the wood slender, with hardly any appearance of buds in the axile of the leaves, they term water-shoots. As soon, in the growing season, as the character of both these sorts of shoots, especially of the latter, is known, they ought to be pinched off, with the exception of some cases, at the discretion of an intelligent pruner, where the gourmand may fill up a vacancy, supply a decaying branch, or otherwise be so situated as to assist in forming the tree. This chiefly happens when they are thrown out on the sides of wall-trees, so as to admit of being checked by a horizontal or oblique position in training. What are called fore-right and back shoots, or such as are thrown out nearly at right angles to the training surface, ought to be rubbed or pinched off, as ill adapted for training, or being applied to the training surface; but with the same exceptions as for gourmands. Where the grand object is fruit, however, it is well remarked by Marshall (Introd. to Gard.), "that in this matter, the end in view is not to be sacrificed to fanciful precision."

2130. Pruning to promote the formation of blossom-buds depends on the nature of the tree. The peach and nectarine, for example, produce their blossoms on the preceding year's wood; consequently the great art of pruning a peach-tree is to have a regular distribution of young wood over every part of it. This the tree has a natural tendency to effect itself, and all that is required from the pruner is, when these shoots are too abundant, to rub them off in the summer pruning, and where they are too few, to cut or shorten some of the least valuable branches or shoots in the winter pruning. In apples and pears, on the contrary, the blossoms are chiefly produced on short leafy protuberances, called spurs, which form themselves naturally along the sides of the shoots, chiefly of apples and pears, but also of plums, cherries, quinces, medlars, and to a certain degree, the apricot, which produces blossoms on last year's wood, and on spurs and small twigs from the shoots of the second year preceding. The production of bearing or blossom buds is sometimes promoted by cutting out weak wood, by which what remains is strengthened; and shortening or stopping the shoots of the vine in summer is believed by many to have the same effect. The rose, syringa, spiraea frutex, and many shrubs, produce their blossoms in the wood of the present year, and to give
vigor to such plants, it is desirable, when blossoms are wanted in these shrubs, to cut down both old and new wood.

2131. Pruning for the enlargement of the fruit is effected either by diminishing the number of blossom-bearing branches, or shortening them; both which operations depend on the nature of the tree: the mode of shortening is particularly applicable to the vine, the raspberry, and to old kernel fruit-trees.

2132. Pruning for adjusting the stem and branches to the roots is almost solely applicable to transplanted trees, in which it is an essential operation; and should be performed in general in the interval between removal and replanting, when the plant is entirely out of the ground. Supposing only the extremities of the fibres broken off, as is the case in very small plants and seedlings, then no part of the top will require to be removed; but if the roots have been broken or bruised in any of their main branches or ramifications, then the pruner, estimating the quantity of root of which the plant is deprived by the sections of fracture and other circumstances, peculiar and general, will be able to form a notion of what was the bulk of the whole roots before the tree was undisturbed. Then he may state the question of lessening the top to adjust it to the roots thus:—As the whole quantity of roots which the tree had before removal is to the whole quantity of branches which it now has or had, so is the quantity of roots which it now has to the quantity of top which it ought to have. In selecting the shoots to be removed, regard must be had to the ultimate character the tree is to assume, whether a standard, or trained fruit-tree, or ornamental bush. In general, bearing-wood and weak shoots should be removed, and the stronger lateral and upright shoots, with leaf or shoot eyes, left.

2133. Pruning for renewal of the head is performed by cutting over the stem a little way, say its own thickness, above the collar or the surface of the ground. This practice applies to old osier-beds, coppice-woods, and to young forest-trees. Sometimes also it is performed on old or ill-fruiting fruit-trees, which are headed down to the top of their stems. This operation is performed with the saw, and better after scarification, as in cutting off the broken limb of an animal. The live section should be smoothed with the chisel or knife, covered with the bark, and coated over with grafting clay, or any convenient composition which will resist drought and rain for a year.

2134. Pruning for curing disease has acquired much celebrity since the time of For-syth, whose amputations and scarifications for the canker, together with the plaster or composition which he employed to protect the wounds from air, are treated of at large in his Treatise on Fruit Trees. Almost all vegetable diseases either have their origin in the weakness of the individual, or induce a degree of weakness; hence to amputate a part of a diseased tree is to strengthen the remaining part, because the roots remaining of the same force, the same quantity of sap will be thrown upwards as when the head and branches were entire. If the disease is constitutional, or in the system, this practice may probably, in some cases, communicate to the tree so much strength as to enable it to throw it off; if it be local, the amputation of the part will at once remove the disease, and strengthen the tree.

For the removal of diseases, whole branches, the entire head, single shoots, or merely the diseased spot in the bark or wood, may require to be cut off. In the removal of merely diseased spots, care must be taken to remove the whole extent of the part affected with a part of the sound wood and bark; and, in like manner, in amputating a diseased shoot or branch, a few inches or feet of healthy wood should be taken away at the same time, to make sure of removing every contamination.

Insects may be removed, or at least prevented from spreading on trained trees, especially such as are in houses, and on dwarf-trees, where the whole plant comes readily under the eye, either by cutting off, in the summer season, the young shoots or the individual leaves on which the insects, as the coccus, aphis, acarus, &c. are found. This is frequently practised on gooseberry-plants, and Sir Brook Boothby (Hort. Trans. vol. i.) asserts that he keeps his peach-trees free from the red spider by cutting off every leaf the moment he sees an insect on it.

2155. Pruning the roots of trees. What effect it would have on the roots of trees, if they could be exposed to view, and subjected to pruning and training, as well as the branches, it is not easy in many cases, to determine; but where they are diseased, or growing on soil with an injurious substratum, could the pruning-knife be applied to their descending and diseased roots annually, the advantages would be considerable. The practice of laying bare the roots of trees to expose them to the frost, and render the tree fruitful, is mentioned by Evelyn and other writers of his time; but in doing so, it does not appear that pruning was any part of their object. The pruning of roots can therefore only take place, according to the present state of things, in the interval between taking up and replanting; as such roots are generally small, and some of them broken or injured, all that the pruner has to do, is to facilitate the healing of the ends of broken roots by a more perfect amputation; and in fruit-trees he may shorten such roots as have a tendency to strike too perpendicularly into the soil. The form of the cut in either case is a matter of less consequence than in the shoot; but like it, it ought in general to be made from the under side of the shoot, that only one section may be fractured, and that the removed section may be the fractured one; and also that water or sap may rather de-
scend from than adhere to the wound. The chief reason for this practice, however, is the facility of performing it, for a section directly across, as if made with a saw, will, in roots, heal as soon, if not sooner, than one made obliquely; but to make such a section in even small roots would require several distinct cuts, whereas the oblique section is completed by a single operation. The Genoese gardeners, in pruning the roots of the orange-trees, always make a section directly across, which, in one year, is in great part covered by the protruding granulated matter. (See 1886).

The roots of trees might be completely pruned, if done by degrees; say that the roots extended in every direction in the form of a circle; then take a portion, say one eighth, of that circle every year till it is completed; and remove the earth entirely from above and under the roots; then cut off the diseased parts, or those roots which penetrate into bad soil; and laying below them such a stratum as shall be impenetrable by them in future, intermix and cover them with suitable soil.

2136. Pruning herbaceous plants, or what is called trimming, consists generally in thinning the stems to increase the size and flowers of those which remain; but it may also be performed for all the purposes before mentioned; and for some other purposes, such as the prolongation of the lives of annuals by pinching off their blossoms, strengthening bulbous roots by the same means, increasing the lower leaves of the tobacco-plant by cutting over the stem a few inches above ground, &c. In trimming the roots of herbaceous plants, the same general principles are adopted as in pruning the roots of trees. In transplanting seedlings, the tap-root merely requires to be shortened; and in most other cases merely bruised, diseased, or broken roots cut off, and fractured sections smoothed.

2137. The seasons for pruning trees are generally winter and midsummer; but some authors prefer spring, following the order of the vegetation of the different species and varieties. According to this principle, the first pruning of fruit-trees begins in February with the apricot, then the peach, afterwards the pears and plums, then the cherries, and lastly the apples, the sap of which is not properly in motion till April. Some have recommended the autumn and mid-winter; but though this may be allowable in forest-trees, it is certainly injurious to tender trees of every sort, by drying and hardening a portion of wood close to the part cut, and hence the granulous matter does not so easily protrude between the bark and wood, as in the trees where those parts are furnished with sap. For all the operations of pruning, therefore, which are performed on the branches or shoots of trees, it would appear the period immediately before, or commensurate with, the rising of the sap, is the best.

2138. Summer pruning commences with the rubbing off of the buds, or disbudding, soon after they have begun to develop their leaves in April and May, and is continued during summer in pinching off or shortening such as are farther advanced. It is obviously, to a certain extent, guided by the same general rules as winter or general pruning; but the great use of leaves in preparing the sap being considered, summer pruning wisely conducted will not extend farther than may be necessary to maintain as much as possible an equilibrium of sap among the branches; to prevent gourmands and water-shoots from depriving the fruit of their proper nourishment, and to admit sufficient air and light to the fruit. Most authors are of opinion, that the other objects of pruning will be better effected by the winter operations. Summer pruning is chiefly applicable to fruit-trees, and among these to the peach; but it is also practised on forest and ornamental trees when young, and is of great importance in giving a proper direction to the sap in newly grafted trees in the nursery.

2139. Thinning the branches of individual trees may be considered as included in pruning. In herbaceous vegetables, or young trees growing together in quantities, it consists in removing all such as impede the others from attaining the desired bulk, form, or other properties for which they are specially cultivated, and is generally performed in connection with weeding or hoeing.

Subsect. 4. Training.

2140. By training is to be understood the conducting of the shoots of trees or plants over the surface of walls, espalier rails, trellises, or on any other flat surface. It is performed in a variety of ways, according to the kind of tree, the object in view, and the particular opinions of gardeners.

2141. The object of training is, either to induce a disposition to form flower-buds in rare and tender trees or plants; to mature and improve the quality of fruits which would not otherwise ripen in the open air; or to increase the quantity and precocity of the fruit of trees which mature their fruit in the open air. Such are the principal objects of training; which are effected by the shelter and exposure to the sun of the surface to which they are trained, by which more heat is produced, and injuries from severe weather better guarded against; by the regular spreading of the tree on this surface, by which the leaves are more fully exposed to the sun than they can be on any standard; and by the form of training; which, by retarding the motion of the descent of the sap, causes it to spend itself in the formation of flower-buds.

2142. The leading modes of training woody-stemmed trees are the fan, horizontal, and vertical (fig. 386. a, f, h). To which may be added the wavy or curvilinear. Their varieties are, the herring-bone (a), the irregular fan (b), the stellate fan (c), the drooping
fan (d), the wavy fan (e); the horizontal, with screw stem (g), and with double stem (k); the vertical, with screw or wavy shoots (h), and with upright shoots (i). Haywood proposes a sort of wavy training (fig. 387.), little different from that of the wavy fan, but which is certainly superior to some of the other of the above modes in principle, as it has no tendency to constrain the shoots, and produce an irregular distribution or exhibition of the sap in gourmards, &c. (Science of Horticultrue, 8vo. 1818.)

2143. Trees with flexible stems, such as the vine and other climbers, admit of three other varieties of training (fig. 388.), which, as vines bear the sweetest fruit at the greatest distance from the root, is particularly suitable for them.

2144. Fan training, as the name imports, directs the spreading out of all the branches like the spokes of the fan: it is reckoned of universal application and peculiarly suitable for peaches and other stone-fruits.

2145. Horizontal training is that in which, from a main stem, lateral branches are led out horizontally on each side, and is more especially adapted for pear-trees.

2146. Horizontal training with the screw stem is chiefly applicable to pears and apples, and the use of the screw is to cause buds to push at proper places for the horizontal shoots. Where this is not adopted, the annual heading down of the vertical shoot is resorted to, by which the same effect is produced; but the tree requires in this case a longer period to fill the wall. It may be effected either with one or two main stems; but, in ge-
nereal, the latter mode is preferable (fig. 389.), as distributing the sap or vigor of the tree more equally.

2147. Oblique training resembles the two last, with this difference, that the lateral shoots are trained obliquely to the main stem. It is particularly adapted for cherries. Thouin remarks, that the shoots should not be raised above an angle of forty-five degrees, unless in the case of a very weak shoot, which, for one season, may be led perpendicularly; nor lowered below the horizontal line, unless in the case of an excessively strong gourmand or water-shoot. The angle of forty-five degrees indeed is recommended by the French writers, as the best for all shoots of fruit-trees to assume, whether by the training against walls or the pruning of standards. See the articles Espalier and Treille in Cours Complet d’Agriculture, &c.

2148. Perpendicular training is performed by leading one horizontal shoot from each side of the stem, and within a foot or eighteen inches of the ground; the shoots which proceed from these are led up perpendicularly to the top of the wall; sometimes such shoots are trained in the screw or serpentine manner, particularly in vines and currants, which bear remarkably well in this form. This is the original mode of training practised by the Dutch, and is still more common in Holland and Flanders than any where else.

2149. Stellate training refers chiefly to standards trained on walls, or what by some are called riders. The summit of the stem being elevated six or eight feet from the ground by its length, the branches are laid in like radii from a centre.

2150. The open fan (fig. 390.) is a mode of training described by Professor Thouin, and exemplified in the Jardin des Plantes. It does not appear to differ much from a mode described by Knight, which he applied to the peach, and considers, with a little variation, applicable, even with superior advantages, to the cherry, plum, and pear-tree. This form, he adds, "might with much advantage be given to trees whilst in the nursery; and perhaps it is the only form which can be given without subsequent injury to the tree." There is nothing very peculiar in this form the first and second year of training (a, b), after being headed down; but in the third year (c), the reversing of the lateral shoots (d), becomes a characteristic.

2151. Wavy or curvilinear training, Haywood considers as combining "all the grand requisites stated to be produced" by the modes recommended by other writers on fruit-trees. "The stems (fig. 391. a) being two principal branches through which the sap will flow in equal portions from the root, to the length of three feet, before it is permitted to form collaterals, the same effect will be produced as if the whole sap was to pass up a single stem of a standard of six feet, which is justly observed by Bradley, 'to make fruit-branches in such plenty, that hardly any barren shoots are to be found upon them.' It also is conformable to the idea of Hales, that 'light, by freely entering the extended surfaces of leaves and flowers, contributes much to the ennobling the principles of vegetables.' By avoiding the precise horizontal position in which Hitt
directs the branches to be fixed, the sap is more regularly and uniformly disposed of, and there will be no necessity for cutting branches short to form studs for producing bearers, nor to adopt the method recommended by Forsyth for furnishing bearers, that of repeatedly pinching off the tops, and shortening the leading shoots. The whole of the sap will, by this mode, be expended in profitable and increasing production, and all the desirable effects which these authors describe to be attainable, will be produced in less time and with less difficulty. By this mode, also, it is possible to train a tree to its utmost extent without ever using the knife for any other purpose than for removing worn-out branches, or old bearers, nor need a branch ever be shortened. It will be found likewise to support Knight’s ideas, and expose a greater surface of leaf to the light, in the shortest possible time. It will also promote an equal distribution of the circulating fluids; and without cutting off the strongest and weakest branches, each annual shoot, as produced, will possess nearly an equal degree of vigor. And, as the horizontals will be formed of the most luxuriant shoots, they will find sufficient space to be trained in; and thus by proper treatment, will, in due season, be found to have uniformly produced the finest possible bearing wood for the succeeding year, and this without pinching off shoots. Thus, also, the same square of walling will be furnished with more bearing wood, in the third and fourth years, than can possibly be done by any other mode, and than can be effected by the common mode of practice, in less than eight or ten years.”

2152. Preparatory training. Nearly the same routine is gone through when the trees are young, for all the different modes of training. The shoots of grafted trees newly received from the nursery (fig. 392. a) are not shortened by the best modern practitioners: at the end of the first season the side branches are left at an elevated angle (b), to encourage them to throw out laterals; afterwards they are brought down (c, d) to an oblique or nearly horizontal position, and each shoot, placed in its final position, as it increases in size.

![Diagram](image_url)

2153. Materials used in training. The operation of training on walls is performed chiefly by means of nails and shreds, on trellises by bass ties, and on espalier rails osier-twigs are most commonly used. The bass, after being applied, is gently twisted round with the finger and thumb, in order that it may run into a firm knot without tearing and weakening the ligament. The osier tie is made fast by twisting the two ends, somewhat in the manner done by reapers in tying up sheaves of corn, and well known in the nurseries. But the nicety of the operation of training consists in the proper use of nails and shreds on a wall; in which business, as Marshall has observed, “ingeniousness will evidence itself in neatness and symmetry.” When a shoot requires some constraint to retain it in its position, the pressure must always be against the shred and never against the nail. Of both nails and shreds there should be two sizes used, the larger for strong, and the smaller for weak shoots. Trees trained to boards can hardly have nails too small; and those trained to stone or old brick walls generally require a larger size.

2154. Shreds should be adapted to the strength of the branches, and the distance of the buds from each other; so that with strong shoots, having their buds wide, such broad shreds may be used as would make weak shoots unsightly, and spoil them by covering the buds; many a well cut tree has been made disgusting, merely by irregular and dangling shreds. A uniformity of color can hardly be accomplished, but a regularity of size may; scarlet, if all alike, looks best, and white the worst. The general width of shreds should be from half an inch to three quarters, and the length two inches to three, having some wider, longer, and stronger, for large branches. In the disposition of shreds, some must have their ends turned downwards, and some upwards, as best suits, for bringing the shoots to their proper place, and straight direction. Though some pruners observe a sort of alternate order, yet the ends hanging chiefly down will look best. Use no more shreds and nails than necessary to make good work, as the effect is rude and injurious. As nails are apt to break out pieces of the wall in drawing, it is a good way to give the nail a
taps to drive it a little, which loosening it from its rust, makes it come out easier, and so saves a wall from large holes, which is a material thing. (Introd. to Gard.)

2155. Herbaceous training is performed by means of poles, rods, branches, and pegs. Plants that twine and grow high are furnished with high poles, on which to twine themselves, as the tamis, convolvulus, &c. Plants with tendrils, as the pea, the bryonia, &c. are furnished with branches or spray, through which the plant springing up attaches itself by its tendrils, and is thus better exposed to the sun and air, and not so liable to rot as when it lies on the ground. Props or poles are used for supporting and leading upright, tall, slender, growing plants, as the dahlia, tree-lupin, and the like. Creeping and trailing plants, as the melon, gourd, &c. are generally trained in the stellate manner on the ground by means of pegs; sometimes also on walls and trellises.

Subsect. 5. Blanching.

2156. Blanching is an operation of culture performed by earthing the stems of plants, by tying up their leaves, or by covering them with utensils from the light.

2157. Blanching by earthing is performed on the celery, chardoon, asparagus, &c. In the case of annuals the earth is generally drawn up so as to press on the leaves of the plant as it advances in growth; in the case of perennials a covering of loose earth is generally placed over them before the growing season, through which the stalks shoot up, and are blanched.

2158. Blanching by tying together the leaves is sometimes performed on lettuce, cabbage, endive, &c. The plant being nearly in its most leafy state, the head or fasciculus of leaves are gathered together, and tied up with bass ribands. By this operation two effects are produced: the inner leaves as they grow, being excluded from the light, are blanched; and being compressed in proportion to the growth, which takes place after tying up the head, the fasciculus becomes both tender and solid.

2159. Blanching by overlaying is merely the laying down of tiles, slates, pieces of boards, &c. on endive and other salading, when nearly full grown, and of which, being thus excluded from the sun, the future growth is colorless. Covering by the following mode is preferable.

2160. Blanching by covering with utensils is a recent invention applied to sea-kale, rhubarb, asparagus, &c. and consists in placing over them the utensils already described as appropriated to this purpose. (1427.)

Sect. IV. Operations for inducing a State of Fruitfulness in barren and unblossoming Trees and Plants.

2161. Various means have been tried to induce fruitfulness with different degrees of success. Almost every description of fruit-tree, if planted in a thin stratum of rich loam on a dry and impervious sub-soil, will come into bearing in regular course, according to its nature; but it too frequently happens that the stratum of soil is too deep, or the roots penetrate into the sub-soil, or by some means, not always obvious, acquire the power of throwing much superfluous sap into the tree, which spends itself in leaves and branches, instead of blossoms. Similar circumstances produce similar effects in ornamental trees and shrubs, whether in the open air or in artificial climates. Attempts are known to have been made for upwards of a century and a half, to cause such trees to produce blossoms, attended with different degrees of success; but the practice was carried on empirically, without any knowledge of the reason or principle which operated in producing the desired end, till its true rationale was given by Du Hamel, in his Physique des Arbres, 1758.

2162. Laying bare the roots of trees is mentioned by Evelyn as conducive to fertility. — Transplanting the tree frequently, by Van Osten. — Boring a hole, and driving in an oak plug is mentioned by the same author as the “old way.” Every one must have observed that trees partially blown out of the ground, or with the earth washed or otherwise removed from their roots in banks or river-sides, or with their trunks or roots broken, bent, or mutilated in any way, are always more fruitful than others; and this, we conceive, has suggested the various modes of artificial mutilation. Mutilation, both in plants and animals, is attended by a sort of maturity; and maturity in all living things is the period of reproduction.

2163. Cutting the roots of trees is an old practice, generally performed in winter or spring, but recently by Beattie, gardener at Scone, in midsummer. “In the beginning of July 1811, I had a border on the south wall, of 400 feet long, trenched to the depth of from two and a half to three feet; in doing this, I had the opportunity of cutting the roots of all the trees, as the work went on, which I did so completely, that they in a manner hung by the nails and shreds, with a ball of earth of about two feet from the stem of the tree. As cutting the roots of fruit-trees has a tendency to make them fruitful, that may possibly proceed from the small quantity of fibrous roots produced by the operation.” Beattie says, he acted on the principle of depriving the tree of the means of containing such a great quantity of sap, thereby preventing it from
growing so much to wood, and of course inclining it to become fruitful. (Caled. Mem. vol. i. 272.) Nicol suggests the same expedient in his Forcing and Fruit Gardener, 4th edit. p. 240.

2164. Cutting notches in the stem or branches has been tried on many occasions on the same principle as cutting the roots.

2165. Partial decortication is the removal of the bark already scaling off, covered with mosses and lichens, or carbonised by the action of the atmosphere. It is only applicable to old trees, or trees of a certain age, and the effect is to increase the vigor of the tree, and thus promote the production of young wood and blossom-buds. It was recommended by Arnaud d'Andilly, in 1650, and has been practised for several years, by Forsyth, Lyon, and various others, on standard-trees, and by King, a commercial gardener, at Teddington, on the vine.

2166. Stripping off pieces of the bark from the stem and branches is said by Marshall to check the luxuriance, and promote the fruitfulness of pear-trees. (Intro. to Gard. &c. 4th edit. p. 156.)

2167. Ringing the stem and branches, circumcision, or excision, &c. was known to the Romans, and is mentioned by Virgil, Columella, &c. Among the moderns, it seems to have been revived by Du Hamel in the beginning of the 18th century, more especially in 1733, when he perfectly succeeded in rendering trees fruitful, and has given an account of his experiments in the Mémoires de l'Académie des Sciences, A. D. 1788. The subject has since been taken up by Suriray Delarue, and by Lancrey; the former of whom has given an excellent history and rationale of the practice in the Journal Physico-Économique for 1803. It is also ably treated in the Cours Complet d'Agiculturre, &c. art. Bourselet. The effect of ringing has been perfectly well known and acted on in Holland and Germany since Du Hamel's time, as any one may be assured of by the perusal of the works of Christ, Diederich, and Diel; and it is remarkable, that so late as 1815, A. Hempel, a clergyman of Saxony, should have published an account of his practice in ringing, as new. The use of ringing would be, in all probability, introduced into England soon after Du Hamel's experiments were published; but though it has been known and occasionally practised by some gardeners for upwards of half a century, it seems not to have been generally known, either in 1817, when, judging from a paper of Dr. Nölden, the subject was considered new in the Horticultural Society; or, in the end of last century, when Dr. Darwin, in his Notes to Phytologia, vol. i. p. 393, describes the practice, and accounts for its effects. It is now frequently practised, both for the purpose of inducing blossoms on trees, or rendering them productive; and for accelerating the maturity and increasing the size of fruits. The former has been termed production-ringing, and the latter maturation-ringing. (Hort. Trans. iv. 557.) Production-ringing should be performed in the spring, and will produce its effects in the following year: maturation-ringing when the plants are in blossom, and it will show its effects the same season.

2168. Maturation-ringing. Ringing has been found not only to induce blossom-buds, but where these prove fertile, to increase the size and accelerate the ripening of fruits. In a paper read before the Horticultural Society in 1808, Williams, of Pitmaston, describes a mode of making annular excisions in the bark of vines. These were made rather less than a quarter of an inch in width, that the exposed wood might be covered again with bark by the end of autumn. "Two vines of the white Frontiniac, in similar states of growth, being trained near to each other on a south wall, were selected for trial; one of these was experimented on (if I may use the term), the other was left in its natural state, to form a standard of comparison. When the circle of bark had been removed about a fortnight, the berries on the experimented tree began evidently to swell faster than those on the other, and by the beginning of September showed indications of approaching ripeness, while the fruit of the unexperienced tree continued green and small. In the beginning of October, the fruit on the tree that had the bark removed from it was quite ripe, the other only just began to show a disposition to ripen, for the bunches were shortly afterwards destroyed by the autumnal frosts. In every case in which circles of bark were removed, I invariably found that the fruit not only ripened earlier, but the berries were considerably larger than usual, and more highly flavored. The effects thus produced, I can account for only by adopting Knight's theory of the downward circulation of the sap through the bark. It is not of much consequence in what part of the tree the incision is made; but in case the trunk is very large, I should then recommend, that the circles be made in the smaller branches."

2169. The operation of maturation-ringing should be deferred till the flowers are fully expanded, or rather till they are passing into fruit, or even till the fruit is set. The sap, being interrupted in its descent by the annular incision, is held in the bough, and thus the fruit gains a more ready and uninterrupted supply of nourishment, the consequence of which is not only an increase of size, but earlier maturity. This operation, besides, may be serviceable in ripening the seeds of plants, which otherwise would not be per-
INDUCING FRUITFULNESS.

2170. Ringing is said to force young trees to show blossoms. Hempel states as a consequence resulting from ringing, that you may force young trees to show fruit, before they otherwise would do. That ringing may have some effect in this way, we think highly probable; but by no means so much as is ascribed to it by Hempel. Trees must arrive at their age of puberty, like animals, before they can propagate their species. Abundance of food and heat will, no doubt, induce a degree of precocity in the subjects of both kingdoms; and as ringing gives in effect abundance of food to the particular part above the excision, it must have some effect, but it has not been proved to have much. Ringing will produce blossoms in all plants, herbaceous or shrubby, propagated by extension, that is, originated otherwise than from seed, at any age; but its effects on young trees raised from seed, or in causing blossoms on any description of tree to set, are much less certain; though in all cases where they do set, the size of the fruit will be greatly enlarged for the first year or two.

2171. In performing the operation of ringing, a ring of outer and inner bark, not larger than the tree can fill up in stone-fruit in one, and in kernel-fruit in two, or at most three years, is cut clean out with a knife, or the ringing shears. (fig. 123.) If larger, the tree becomes too much excited to fruitfulness, and the part of it separated from the root by the ring dies, while the stem and parts adjoining the root become too luxuriant. When the rings are made so wide as that the barks cannot unite for two or three years, the result, says the author of the article, Bourrelet, in N. C. d'Agriculture, &c. will be to "accelerate the production of blossoms, and the setting of fruit, and to augment their size during the first year; and then, during the following years, to make them languish, and at last die." "There is a pear-tree," Sabine observes, "against one of the walls in the kitchen-garden, belonging to his Majesty, at Kew, which underwent the operation of ringing about fifteen years ago. The part operated on was near the root; and, as it was a principal arm, about one half of the whole tree became influenced by the operation. This half has uniformly borne fruit, the other half has been nearly barren. The portion of stem which was laid bare is about six inches wide, and it has not been again covered by bark. That part just above the ring is considerably larger than the part below it. The ends of the branches appear in much decay, and there are but very few young shoots thrown out from the sides; whilst, on the other part of the tree, the shoots, as usual, proceed from the extremities, as well as from the sides of the main branches. I apprehend, from the present appearance of the whole, that the portion of the tree which, by the separation of the bark, has been deprived in a great measure of supply from the root, cannot survive many years."

2172. Renewal of the soil about fruit-trees has been found by Hay, of Newliston, near Edinburgh, in the case of peaches; and Maher, of Arundel, in the case of figs, and by various others, to renew the fruitfulness of trees. There may be two reasons given for this, both of which may be concerned in the effect: the first is the exhaustion of the soil generally; and the second is its exhaustion of the particular sort of food preferred by the kind of tree. Though we are not so certain that every species of tree requires, to a certain extent, a particular sort of food, as we are that herbaceous vegetables, as wheat, oats, &c. do; yet analogy renders the fact highly probable. At any rate, it is clear that a renewal of soil must always be conducted with reference to the state of the plants; a poor, limy, sandy soil may be substituted for one where the luxuriance of the plants shows that it is too rich; and a rich loamy one for one of an opposite description, where the plants are unthriving, &c.

2173. Bending down the branches has been found conducive to fruitfulness; and is accounted for on the same principle as ringing. It has been well exemplified by Mayer (Hort. Trans. i.), in fixing clay balls to the extremities of the shoots of young apple-trees after midsummer, which, depressing them, stagnated the sap, and induced the production of abundance of flower-buds.

2174. To induce the production of blossoms in herbaceous plants, any or all of the above modes may be adopted with most species, but on a large scale the first object is to place the plants in a soil neither too poor nor too rich. A dry soil, not deep, and resting on a dry firm bottom, is most favorable to fruitfulness, especially when joined to abundance of air and light. In perennials, the effect can only be produced the second year, as in trees; but in annuals it will be immediate: in the former class, however, where the defect is want of nourishment, the effect may take place even the first year. Knight induced the production of blossoms on an early variety of potatoe, by depriving the plant of its tubers, as soon as they made their appearance; by which means, the nourishment
which would have been devoted to their enlargement, was employed by the plant in the production of blossoms, as the remaining mode which it had of propagating its species. The reverse of the practice is found proportionally to increase the bulk of the tubers, and has become an important point of practice in potatoe culture. The Dutch, as Darwin informs us, were the first to adopt this mode in the culture of bulbous-rooted flowers. In general, it may be stated, that the art of producing blossoms in perennial herbaceous plants consists in permitting them to have abundance of leaves, fully exposed to the light and air the preceding year, and in not cutting them over when in a state of growth, as is too frequently done, but in letting them first begin to decay. By this means, healthy vigorous buds and roots are prepared for exertion the following year.

2175. General estimate of, these practices. All these operations may be resorted to occasionally as expedients, but the only permanent and general mode of inducing fruitfulness is by supplying judicious soil, exposure, and pruning.

Sect. V. Operations for retarding or accelerating Vegetation.

2176. To overcome difficulties is the last stage in the progress of art. After civilised man has had every thing which he can desire in season, his next wish is to heighten the enjoyment by consummation at extraordinary seasons. The merit here consists in conquering nature; and in gardening this is done by cold-houses and hot-houses, and by excluding or increasing the effects of the sun in the open air. The origin of these practices is obviously derived from the fact, that heat is the grand stimulus to vegetation, and its comparative absence, the occasion of torpor and inactivity.

Subsec. 1. Operations for retarding Vegetation.

2177. Retarding by the form of surface, is effected by forming beds of earth in an east and west direction, sloping to the north at any angle at which the earth will stand; here salading may be sown in summer, and spinach, turnips, and such crops as shoot rapidly into flower-stems during hot weather.

2178. Retarding by shade. The simplest mode of retarding vegetation is, by keeping plants constantly in comparative shade in the spring season. This is either to be done by having them planted in the north side of a wall or house, or sloping bank, hill or other elevation; or by moving them there in pots; or by placing a shade or shed over, or on the south side of the vegetables to be retarded. Where the object of retarding vegetation is to have the productions in perfection later in the season, the first method is generally resorted to; but where vegetation is only retarded in order that it may burst forth with greater vigor when the shades are removed, then either of the others is preferable. Trees on an east and west espalier-rail, shaded from the sun from February to the middle of May, will be later of coming into blossom, and therefore less likely to have their blossoms injured by frost.

2179. Retarding by the cold-house, or ice-cold chamber, (figs. 169, 173.) is more particularly applicable to plants in pots, especially fruit-trees, and might be made a practice of importance. Vegetation may in this way be retarded from March to September, and the plant removed at that season, by proper gradations, to a hot-house, will ripen its fruit at mid-winter. It is even alleged by some gardeners, who have had experience in Russia, that the vegetation of peach-trees may be so retarded an entire year; and that afterwards, when the plant is removed into spring or summer heat, in the January of the second year, its vegetation is most rapid, and a crop of fruit may be ripened in March or April, with very little exertion on the part of the gardener. The earliest potatoes are obtained from tubers which have been kept two seasons; that is, those are to be planted which have been produced the season before the last; or, the produce of summer 1821, in December 1822.

2180. Retarding the ripening of fruits by excluding oxygen. M. Berard, of Montpelier, in an essay on the ripening of fruits, which gained the prize of the French Academy of Sciences in 1821, found that the loss of carbon is essential to the ripening of fruits; that this carbon combines with the oxygen of the air, and forms carbonic acid; and that when the fruit is placed in an atmosphere deprived of oxygen, this function becomes suspended, and the ripening is stopped. Hence it results, that most fruits may be preserved during a certain period, by gathering them a few days before they are ripe, and placing them in an atmosphere free from oxygen. The most simple process for effecting this consists in placing at the bottom of a bottle, a paste formed of lime, sulphate of iron, and water; then introduce the fruit so as they may rest detached from the bottom of the bottle, and from each other, and cork the bottle and cover it with cement. Peaches, plums, and apricots have been kept in this way for a month; pears and apples for three months. Afterwards they will ripen perfectly by exposure to the air. (Journal R. Inst. vol. xi. 396.)
ACCELERATING VEGETATION.

CHAPTER IV.

SUBSECT. 2. Operations for accelerating Vegetation.

2181. Accelerating by the form of surface consists in forming beds or banks in an east and west direction, and sloping to the south, forming an angle with the horizon, the maximum of which, in garden-soils, cannot exceed 45 degrees. On such beds early sown crops, as radishes, peas, turnips, &c. will come much earlier, and winter standing crops, as lettuce, broccoli, &c. suffer less from severe weather than those on a level surface. The north side of such beds or ridges may be used for retarding vegetation, as leeks, borage, &c. (2177.)

2182. Acceleration by shelter, and exposure to the sun, is the simplest, and probably only primitive mode of accelerating the vegetation of plants; and hence one of the objects for which walls and hedges are introduced in gardens. A May-duke cherry, trained against a south wall, and another tree, of the same species, in the open compartment of a sheltered garden, were found, by the late J. Kyle, of Moredun, near Edinburgh, on an average of years, to differ a fortnight in the ripening of their fruit. In cold, damp, cloudy seasons, they were nearly on a par; but in dry, warm seasons, those on the wall were sometimes fit to be gathered three weeks before the others. It may be here remarked, that though, in cloudy seasons, those on the wall did not ripen before the others; yet their flavor was, in such seasons, better than that of the others, probably from the comparative dryness of their situation. Corn and potatoes on the south and north sides of a hill, all other circumstances being equal, ripen at about the same relative distances of time.

2183. Accelerating by soils is effected by manures of all sorts, but especially by what are called hot and stimulating manures and composts, as pigeons' dung for cucumbers, blood for vines; and, in general, as to soils, lime-rubbish, sand, and gravel, seem to have the power of accelerating vegetation to a much greater degree than rich clayey or loamy soils, or bog or peat earth.

2184. Accelerating by previous preparation of the plant is a method of considerable importance, whether taken alone, or in connection with other modes of acceleration. It has long been observed by cultivators, that early ripened crops of onions and potatoes sprout, or give signs of vegetation, more early next season than late-ripened crops. The same of bulbs of flowers which have been forced, which re-grow much earlier next season, than those which have been grown in the open air. It was reserved to Knight, however, to turn this to account in the forcing of fruit-trees, as related in a paper, accompanied as usual by what renders all the papers of that eminent horticulturist so truly valuable,—a rationale of the practice.

2185. The period which any species or variety of fruit will require to attain maturity, under any given degrees of temperature, and exposure to the influence of light in the forcing-house, will be regulated to a much greater extent than is generally imagined, by the previous management and consequent state of the tree, when that is first subjected to the operation of artificial heat. Every gardener knows, that when the previous season has been cold, and cloudy, and wet, the wood of his fruit-trees remains immature, and weak abortive blossoms only are produced. The advantages of having the wood well ripened are perfectly well understood; but those which may be obtained, whenever a very early crop of fruit is required, by ripening the wood very early in the preceding summer, and putting the tree into a state of repose, as soon as possible after its wood has become perfectly mature, do not, as far as my observation has extended, appear to be at all known to gardeners; though every one who has had in any degree the management of vines in a hot-house, must have observed the different effects of the same degrees of temperature upon the same plant, in October and February. In the autumn, the plants have just sunk into their winter sleep; in February they are refreshed, and ready to awake again; and whenever it is intended prematurely to excite their powers of life into action, the expediency of putting those powers into a state of rest, early in the preceding autumn, appears obvious. (Hort. Trans. vol. ii. 393.) Knight placed some vines in pots, in a forcing-house, in the end of January, which ripened their fruit in the middle of July; soon after which the pots were put under the shade of a north wall in the open air. Being pruned and removed in September to a south wall, they soon vegetated with much vigor, till the frost destroyed their shoots. Others, which were not removed from the north wall till the following spring, when they were pruned and placed against a south wall, " ripened their fruit well in the following season in a climate not nearly warm enough to have ripened it at all, if the plants had previously grown in the open air." Peach-trees, some-what similarly treated, unfolded their blossoms nine days earlier, and their fruit ripened three weeks earlier than in other trees of the same varieties. (Hort. Trans. vol. ii. 572.) Pots of grapes which had produced a crop previously to midsummer, were placed under a north wall till autumn; on the 18th of January, they were put into a stove, and ripened their fruit by the middle of April. (Hort. Trans. iv. 440.)

2186. By thus inducing a state of rest in plants in pots, say vines or peaches, in August, and placing them immediately in the ice-cold room till the beginning of January, which is allowing four months of a winter to them, they would, in all probability, produce very early crops of grapes with less forcing than would be required for such as ripen their wood in October. Such pots might be placed in pine and other stoves, where a certain degree of heat is kept at any rate, and might be contrived to produce a succession of fruit, in the manner practised by W. Masland, of Stockport, by a vineyard in pots, which pass in regular succession through his pine-stoves, and furnish ripe grapes the whole year. A state of rest is readily induced by withholding water from plants under cover; and in the open air by covering trees, and a portion of the surface or border around or before them, with canvass or oil-cloth, to throw off the autumnal and part of the winter rains.
2187. **Accelerating by housing,** such as removing plants in pots and boxes, to sheds or rooms in the night, and exposing them in fine weather to the sun, was practised by the gardener of Tiberius, to procure early cucumbers; and by those of Louis XIV. to force peas. (Bénard.) Parkinson and Gerarde describe the practice as applied to raising cucumbers and melons in this country.

2188. **Accelerating by artificial heat in walls** is a very frequent and useful practice. In general it is accompanied by protecting-covers of canvas or netting (1495.); but some gardeners, as Trotter of Alva, a very high and exposed situation on the Ochill hills, never cover their hot-walls; but in ripening the wood in autumn, and in saving the blossom and setting the fruit in spring, keep up such fires as will repel the frost, and evaporate the wet that might fall on the wall. "No danger," Trotter observes, "is to be apprehended from the severity of the spring months, even when exposed to all sorts of weather; every kind of covering being superseded by the genial heat of the wall." This he has long experienced, even in England, but especially in Scotland, to be "the best preservative of the blossom of young fruits." (Caled. Memo. vol. ii. 113.)

2189. **Accelerating by fluided borders** has been occasionally attempted, but can never succeed by fire heat; by tubes of steam, perhaps, something might be done, but the heat can always be more economically applied by means of pots or frames, placed on raised beds of mould, with arches, or some similar contrivance underneath. (See a description of a fluided border in Keil’s Treatise on the Peach Tree, 8vo. 1780.)

2190. **Accelerating by covering with glass cases,** of different sizes and descriptions, probably succeeded to housing. The Romans are supposed to have hastened the ripening of grapes and peaches, by placing them under talc cases (55.); and a French author, Bénard, informs us, that the origin of forcing the vine arose from one Gordon observing that a shoot which had entered his room-window through a crevice, ripened its fruit some time before those branches of the same tree which remained in the open air. The practice of forcing peaches in Holland, is said to have originated from a gardener near Haarlem putting hot-bed lights against his walls to ripen peaches in a bad season. By a mere covering of glass, without any description of bottom heat, or any auxiliary mode of acceleration, almost all fruits and flowers which grow in the open air in this country, may be forwarded from one fortnight to one month, according to the season. Fruits may by the facile means thus afforded of covering and protection, be retained in a ripe and plump state from one to three months; so that in general it may be observed, that cold frames, as they are called, and mere glass cases, will double the ordinary time of enjoying hardy fruits, and certainly they greatly increase the flavor of such as ripen late, and especially of the vine and peach.

2191. **Accelerating by glass cases and artificial heat combined** is effected by hot-beds, pits, and hot-houses.

2192. **Accelerating by the common hot-bed** is an ancient, general, but still somewhat precarious and unmanageable mode. The heat being produced by a fermenting mass of vegetable matter, over which is placed the earth containing the plants, it becomes difficult to regulate any excess of heat, and the plants are sometimes, in the empirical phrase, burnt. When, however, the heat declines, it is readily renewed by linings or a surrounding layer of dung. To remedy the defects of the common hot-bed, and prevent the possibility of burning the plants, by interposing a stratum of air between the dung and the mass of earth which contains them, is the object of the vaulted pit and M’Phail’s frame (figs. 230. 233.) to which there is no objection, but the greater original cost. These structures actually save dung, and are more agreeable to the eye of those who value order and neatness than dung-beds.

2193. **Accelerating by means of walled pits** is very similar to that of forcing by hot-beds; with the advantages of having more room between the surface of the beds and the glass for the tops of shrubs, and of the glass having a better slope; but with the disadvantages of a chance of burning in the first instance, and no power of increasing the bottom heat when it once declines. Bark is generally used to lessen the first evil, as it does not ferment so powerfully as dung, and the second is remedied by a surrounding flue. Such pits are much used in all the branches of garden-culture. Henderson, of Brechin, proposes to lay on the surface of beds of tan, or on hot-beds, pits, pineries, &c. fine drifted river or sea sand, three inches deep. “This covering,” he says, “possesses many advantages. It will expirtrate the slider or wood-louse (oniscus asellus), as the nature of the sand prevents the insect from concealing itself from the rays of the sun. In dung hot-beds, it keeps down the steam. To fruit, it affords a bed as warm and as dry as tiles or slates. This covering also retains the moisture in the earth longer than any other, and is itself sooner dry. It gives the houses a clean, neat appearance, and though it cannot be expected to remove the infection, where already introduced, will be found a powerful preventive of that great evil, mildew.”

2194. **Accelerating by means of hot-houses** is the master-piece of this branch of culture, and is but of modern invention, being unknown till the end of the 17th century. Im-
provement in the form as well as management of these buildings has, as in every other case, been progressive; and there are now a great choice both of the forms adopted, the materials used in the construction of these forms, and the mode of producing artificial heat.

2195. There are two leading modes of accelerating plants in hot-houses; the first is by placing them there permanently, as in the case of the peach, vine, &c. planted in the ground; and the second is by having the plants in pots, and introducing or withdrawing them at pleasure. As far as respects trees, the largest crops, and with far less care, are produced by the first method; but in respect to herbaceous plants and shrubs, whether culinary, as the strawberry and kidneybean, or ornamental, as the rose and the pink, the latter is by far the most convenient method, and it is also the best adapted for affording very early crops. (2185.) Where large pots are used, the peach, cherry, fig, &c. will produce tolerable crops. Knight has observed, that "vines and other fruit-trees, when abundantly supplied with water and manure in a liquid state, require but a very small quantity of mould;" and he adds, "A pot containing two cubic feet of very rich mould, with proper subsequent attention, is fully adequate to nourish a vine, which, after being pruned in autumn, occupies twenty square feet of the roof of a hot-house; and I have constantly found that vines in such pots, being abundantly supplied with food and water, have produced more vigorous wood, when forced very early, than others of the same varieties, whose roots were permitted to extend beyond the limits of the house." (Hort. Trans. vol. ii. p. 373.)

2196. When trees are planted for a permanency within, or close to the outside of a hot-house, the soil requires to be prepared of depth and quality according to the nature of the tree; and a principal consideration is to form, if such does not naturally exist, a sub-soil, which shall be impenetrable to the roots. The depth of soil on such a substratum need not in general be great, provided it be rich. Formerly a depth of three or four feet was recommended; but Hayward proposes to have his fruit-tree borders only fifteen or eighteen inches deep; which is conformable to an observation of Hitt, that the finest crop of peaches he had ever seen, grew on trees which were nourished from a border not more than one foot deep, with a compact rock below. Nicol allows from twenty-four to thirty inches of soil. Knight is of opinion, that "a large extent and depth of soil seem to be no farther requisite to trees than to afford them a regular supply of water, and a sufficient quantity of organisable matter;" and, he thinks, "the rapid growth of plants of every kind, when their roots are confined in a pot to a small quantity of mould, till that becomes exhausted, proves sufficiently the truth of this position." (Hort. Trans. vol. ii. p. 127.)

2197. The operations of forcing chiefly respect the admission of air, the supply of heat, of light, and of water. The grand effect is produced by heat, and the great art is just to supply as much as will harmonise with the light afforded by the sun and the nature of the species of plant to be forced. All the operations of nature are gradual; and a good gardener will always follow these as the safest examples. He will never be anxious to apply artificial heat before buds have naturally swoln; he will then increase the temperature gradually for some weeks; he will in particular guard against any sudden decrease of warmth, it being most necessary towards success, to continue the course of vegetation uninterruptedly, through foliation, inflorescence, and fructification.

2198. Heat and light. An error in hot-house culture in general, of very considerable importance, and which has prevailed till lately, consists in not adjusting the heat of air to the light of the sun. In cloudy weather, and during night, the artificial atmosphere is kept hot by fires and exclusion of the external air, while in clear days and during sunshine, fires are left off or allowed to decline, the external air is admitted, and the atmosphere within is reduced to the temperature of that without. As heat in nature is the result of the shining of the sun, it follows that when there is most light there is most heat; but the practice in forcing is very generally the reverse. "A gardener, in forcing," Knight observes, "generally treats his plants as he would wish to be treated himself; and consequently, though the aggregate temperature of his house be nearly what it ought to be, its temperature, during the night, relatively to that of the day, is almost always too high." In one of Knight's forcing-houses, in which grapes are grown, he always wishes to see its temperature, in the middle of every bright day in summer, as high as 90°; "and after the leaves of the plants have become dry, I do not object to ten or fifteen degrees higher. In the following night, the temperature sometimes falls as low as 50°; and so far am I from thinking such change of temperature injurious, I am well satisfied that it is generally beneficial. Plants, it is true, thrive well, and many species of fruit acquire their greatest state of perfection in some situations within the tropics, where the temperature in the shade does not vary in the day and night more than seven or eight degrees; but in these climates, the plant is exposed during the day to the full blaze of a tropical sun, and early in the night it is regularly drenched with heavy wetting dews; and con-
sequently it is very differently circumstanced in the day and in the night, though the temperature of the air in the shade at both periods may be very nearly the same. I suspect," he continues, "that a large portion of the blossoms of the cherry and other fruit-trees in the forcing-house often proves abortive, because they are forced by too high and uniform a temperature, to expand before the sap of the tree is properly prepared to nourish them. I have, therefore, been led, during the last three years, to try the effects of keeping up a much higher temperature in the day than in the night. As early in the spring as I wished the blossoms of my peach-trees to unfold, my house was made warm during the middle of the day; but towards night it was suffered to cool, and the trees were then sprinkled, by means of a large syringe, with clear water, as nearly at the temperature at which that usually rises from the ground, as I could obtain it; and little or no artificial heat was given during the night, unless there appeared a prospect of frost. Under this mode of treatment, the blossoms advanced with very great vigor, and as rapidly as I wished them, and presented, when expanded, a larger size than I had ever before seen of the same varieties. Another ill effect of high temperature during the night is, that it exhausts the excitability of the tree much more rapidly than it promotes the growth, or accelerates the maturity of the fruit; which is in consequence ill supplied with nutriment, at the period of its ripening, when most nutriment is probably wanted. The muscat of Alexandria and other late grapes are, owing to this cause, often seen to wither upon the branch in a very imperfect state of maturity; and the want of richness and flavor in other forced fruit is, I am very confident, often attributable to the same cause. There are few peach-houses, or indeed forcing-houses of any kind in this country, in which the temperature does not exceed, during the night, in the months of April and May, very greatly that of the warmest valley in Jamaica in the hottest period of the year: and there are probably as few forcing-houses in which the trees are not more strongly stimulated by the close and damp air of the night, than by the temperature of the dry air of the noon of the following day. The practice which occasions this cannot be right; it is in direct opposition to nature." (Hort. Trans. vol. ii. p.130.)

2199. Air. Knight considers that gardeners often and widely err, "by too freely admitting the external air during the day, particularly in bright weather. Plants generally grow best, and fruits swell most rapidly, in a warm and moist atmosphere; and change of air is, to a very limited extent, necessary or beneficial. The mature leaves of plants, and according to Sauvassure, the green fruits (grapes at least), when exposed to the influence of light, take up carbon from the surrounding air, whilst the same substance is given out by every other part of the plant; so that the purity of air, when confined in close vessels, has often been found little changed at the end of two or three days by the growth of plants in it. But even if plants required as pure air, as hot-blooded animals, the buoyancy of the heated air, in every forcing-house, would occasion it to escape and change as rapidly, and indeed much more rapidly, than would be necessary. It may be objected, that plants do not thrive, and that the skins of grapes are thick, and other fruits without flavor in crowded forcing-houses; but in these it is probably light, rather than a more rapid change of air that is wanting. When fruits approach to maturity such an increase of ventilation, as will give the requisite degree of dryness to air within the house, is highly beneficial; provided it be not increased to such an extent as to reduce the temperature of the house much below the degree in which the fruit has previously grown, and thus retard its progress to maturity. The good effect of opening a peach-house, by taking off the lights of its roof, during the period of the last swelling of the fruit, appears to have led many gardeners to over-rate greatly the beneficial influence of a free current of air upon ripening fruits; for I have never found ventilation to give the proper flavor or color to a peach, unless that fruit was at the same time exposed to the sun without the intervention of glass; and the most excellent peaches I have ever been able to raise, were obtained under circumstances where change of air was as much as possible prevented consistently with the admission of light (without glass) to a single tree."

2200. Water. The supplies of water given to plants should be regulated by the supplies of heat, the nature of the plant, its state in regard to growth, and the object for which it is cultivated. Abundance of heat should generally be succeeded by copious waterings, unless the nature of the plant, as its succulency, or its dormant state in regard to growth, render that improper. Plants cultivated for their fruits should be less watered during the ripening season than such as are grown for their effect; a dry atmosphere being most conducive to flavor. The succulent shoots of trees, Knight observes, always appear to grow most rapidly, in a damp heat, during the night; but it is rather elongation than growth, which takes place. The spaces between the bases of the leaves become longer, but no new organs are added; and the tree, under such circumstances, may with much more reason be said to be drawn, than to grow; for the same quantity only of material is extended to a greater length, as in the elongation of a wire.
Sect. VI. Operations to imitate warm Climates.

2201. The imitation of warm climates by hot-houses must not be confounded with the art of forcing the vegetables of temperate climates into the premature production of their flowers or fruit. The former was the first object for which hot-houses were erected, and conservatories, green-houses, and plant-stoves existed in this country before any description of forcing-house; even pineries are of subsequent introduction to botanic and ornamental hot-houses. The various climates and constitutions of plants require atmospheres of different degrees of temperature and moisture: but experience has proved, that the plants of every warm country in the world may be grown in one or other of the three following descriptions of hot-houses:—1. The green-house, of which the varieties are the Sinarium, or house for Chinese plants; the Conservatory, in which the plants are inserted in the soil without pots; the Cold-frame for bulbs, and Heathery for Cape plants, &c. 2. The dry-stove, for succulent plants, or such as require a dry atmosphere; and 3. The moist or bark-stove, for pines, palms, and the tropical plants which require the highest degree of heat, and an atmosphere moist in proportion.

2202. Treatment common to the three species of artificial climates. In general, hot-house exotics are kept in pots; but in some cases, fruit-bearing plants, as the orange, and plants with large roots, as the Strelitzia, and luxuriant creepers, as the different Passifloras, are planted in the ground. The soils are, of course, very various, and can only be treated of with advantage under each species, tribe, or family. There are none of them, however, that will not thrive either in bog-earth, sand, or loam, or a mixture of these. For pines, oranges, and large-blossomed plants, rotten leaves or old cow-dung are added with advantage, and to some of these, as to the orange and pine-apple, liquid manures are frequently applied. Gardeners in general are averse to the application of any thing rich to the soil of exotic plants which are not cultivated for their fruit, a prejudice evidently contrary to analogy, and originating, in all probability in the circumstance, that it is in general desirable to keep exotic plants small, both for want of room in ordinary-sized houses, and by that means to induce a flowering state. Now, however, when the facilities of hot-house building by wrought and cast iron admit of covering several acres of ground with a glass roof at fifty, a hundred feet, or at any distance from the surface; and when the mode of heating by steam readily admits of keeping such a space at any required temperature, all exotic plants, where expense is not an object, may be planted in the ground duly prepared, cultivated and manured like a shrubbery, and allowed to attain their natural size. Such a house or scene may be watered after Loddiges' method already described (1685), and its temperature regulated, if desired, by the ingenious machine of Kewley. (Fig. 217.) With the exception of temperature, the operations in imitation of artificial climates are the same as those for forcing; we shall, therefore, confine ourselves to indicating the temperature of its three leading departments.

2203. The green-house is freely exposed to the influence of our atmosphere when the open air is not colder than 48° of Fahrenheit, and when winds and rains do not prevent the opening of the roofs or other means of ventilation. "As long as the weather continues fair without frost," says Abercrombie, "open the green-house windows in the daytime an hour after sunrise, and close at the same time before sunset. Never admit air by the door or sashes in foggy or damp weather, or when bleak cutting winds prevail. The admission of air in the middle of a clear frosty day will not hurt the plants, if counteracted by fire heat. Admit air freely when the external temperature is at 42° by Fahrenheit, or above; admit it guardedly when between 35 and 42°; but not at all when under 35° before the furnace is employed." Green-house plants are generally placed in the open air during the five mildest months in the year, either by taking off the roofs of the houses when these are moveable, or by removing the pots, and placing them in the open garden.

2204. Dry-stoves are opened night or day in the summer seasons, but only during sunshine in winter and spring, beginning as in the forcing-houses, by opening the top sashes or ventilators first, by which the external air descends and cools down the temperature, partly by mixing with the internal air, and partly by forcing it out. Afterwards, when the temperature of the atmosphere is above 20°, the lower or front sashes or ventilators may be opened, by which means a regular circulation or breeze is promoted in every part of the house, if a detached house; and in most parts of it, if forming part of a range of connected houses.

2205. Moist or bark stoves. The range of temperature which bark-stove plants can endure, "is from 63° to 81° of Fahrenheit, the instrument being in the middle of the house, at a considerable distance from the furnace, and out of reach of the sun's rays." According to Abercrombie the temperature by artificial heat of the bark-stove "is 58° min. 70° max. When meridian summer is felt, the temperature must keep pace with the increase of heat in the atmosphere; and therefore will ascend through all the intermediate degrees, to 75°, 80°, 85°, 90°, 95°, and even 100°. The maximum heat in the house, in July and August, may in general be kept down to 90°, by free admissions of air, and by evaporation from
the water given to the plants; although the force of the season will sometimes prevail to 93° and 105°." McPhail, however, found that pines will bear without injury 130°, and he considers that no plant whatever will be injured by 120°. "It is not uncommon to give air to a hot-house only through the day, and to shut it up close at night, perhaps even increasing the temperature in the evening. Judicious horticulturists reverse the practice. Knowing, for example, that, in the West Indies, chilly and cold nights usually succeed to the hottest days, they rather imitate nature, by shutting up the house during the day, and throwing it open at night. This practice, however, can only be followed in our climate in the summer and autumn seasons." (Nelé, in Ed. Encyc. art Hort.) This opinion is in unison with Knight's, who considers excess of heat during the night, as in all cases highly injurious to the fruit-trees of temperate climates, and not at all beneficial to those of tropical climates; "for the temperature of these is in many instances low during the night. In Jamaica, and other mountainous islands of the West Indies, the air upon the mountains becomes, soon after sunset, chilled and condensed, and in consequence of its superior gravity descends and displaces the warm air of the valleys; yet the sugar-canes are so far from being injured by this sudden decrease of temperature, that the sugars of Jamaica take a higher price in the market than those of the less elevated islands, of which the temperature of the day and night is subject to much less variation." (Hort. Trans. vol. ii. p. 131.)

**Sect. VII. Operations of Protection from Atmospheical Injuries.**

2906. The injuries which plants may receive from the atmosphere, are as various as its changes. Many vegetables which flourish in Britain in the open air during the summer season require protection during some or all of the other seasons of the year. Some also, from the state of their health, or other circumstances, require to be protected from the direct rays of the sun, from excessive rains, winds, frosts, and even from heat and evaporation. From these and other evils the gardener protects by opaque coverings or shelters of different kinds, and by transparent covers or glass cases, and by other operations and processes.

2907. Protecting by fronds and frond-like branches is performed by sticking in the foot-talks of the fronds of any of the ferns, but especially of the pteris aquilina, branches of fir, whin, or broom, or of any other evergreens, between the branches of wall-trees and the wall, so as the frond or leafy branches may project, and either retard the blossom by excluding the sun, as is often done in Denmark and Sweden, or protect it from the frost and winds, as is generally the object in Britain. This is a very simple and economical protection for myrtles, camellias, and other tender botanical plants, trained to walls, or even growing in the open ground as stools, and also for fruit-trees. Archib. Gorrie (Caned. Mem. vol. i. 276.) formed a frame for the more commodiously containing the branches of spruce and silver firs, and other evergreens; and applied frames so clothed to his fruit-tree walls, on the principle of retarding the blossom. The success was equal, and even beyond his expectations. He covered them on the 20th of February, and removed the frames on the 1st of June. During this period, the frames were opened every fine day, but always shut at night. Adjoining were some trees of the same kinds, which were covered night and day, during the above period, with a woollen net. The shoots of these trees were infected with the curl or wrinkled leaf—a disease peculiar to peach-trees in exposed situations; while those protected by the frames of branches were perfectly healthy; and what is remarkable, though retarded nearly four weeks in the period of their blossoming, the fruit ripened one week sooner.

2908. The advantage of using frames in covering by fronds and branches is, that the screens or protecting frames can be removed in the daytime; whereas, attaching the fronds to the trees, they must, in general, remain till they have effected their object. It is easy to conceive that trees so treated must often suffer from want of light, and accordingly Nicol, on the whole, rather disapproves of it. "It is," he says, "a common practice, to screen the blossoms of wall-trees by sticking twigs of larch, or of evergreens, as firs, or lauriers, between the branches and the wall, in such a manner as to even the blossoms where thickest; and some, instead of these, use the leaves of strong fern. These last are certainly fitter for the purpose than the former mentioned, as being lighter, and less liable to hurt the blossoms, when dashed by the wind against them. But all these are objectionable, on account of their shading the blossom too much, and too constantly, from the sun and light, by which it is rendered weak, and the fruit produced often drop away, before arriving to any considerable size; so that all this trouble taken goes for nothing, as there would probably have been as good a crop, had the trees been left to take their chance."

2909. Protecting by straw ropes is effected by throwing the ropes in different directions over the trees, and sometimes depositing their ends in pails of water. It is a Dutch practice, and appears to have been first made known in this country by Dr. Anderson, in his Recreations, &c. in 1804. James Laird appears to have tried it successfully on wall-trees, and on potatoes and other herbaceous vegetables. His method is as follows:—"As soon as the buds of the trees become turgid, I place poles against the wall, in front of the trees, at from four to six feet asunder; thrusting their lower ends into the earth, about a foot from the wall, and fastening them at the top with a strong nail, either to the wall or coping. I then procure a quantity of straw or hay ropes, and begin at the top of one of the outer poles, making fast the end, and pass the rope from pole to pole, taking a round turn upon each, until I reach the end; when after securing the end well, I begin
about eighteen inches below, and return in the same manner to the other end, and so on, till I have reached to within eighteen inches or two feet of the ground. I have also found straw ropes to be very useful in protecting other early crops from the effects of frost, as peas, potatoes, or kidneybeans, by fixing them along the rows with pins driven into the ground. Old herring nets, and branches of evergreens, are not so efficacious as straw ropes, which, besides being much cheaper, may be obtained in every situation."

2210. Protecting by nets is effected by throwing either straw, hay, bess, hennep, or woollen nets over standard-trees, the extreme shoots of which will support the net; or by throwing it over hooped beds, or hooped single plants of herbaceous vegetables, or fixing it over the fruit-trees trained against a wall (fig. 218.), or by placing it over tender flowers and botanic plants, as auricula and hydrangea, &c. by means of net frames or portable cases.

2211. The ordinary way of applying nets, Nicol observes, "is to hang them over the trees, close to the branches; the flower-buds and spurs often sticking out beyond the net. Instead of being hung in an so unmeaning a manner, they should be placed out, at the distance of fifteen or eighteen inches from the tree, being kept off by hooked sticks, with their butts placed against the wall, and at the distance of about a yard from each other. In order to make these stand firmly, the net should be first stretched tightly on, and be fastened on all sides. By further stretching it, to the extent of fifteen or eighteen inches, over the hooked ends of the sticks, it will be rendered so firm that no wind will displace it; and the sticks will also be made quite fast at the same time. If the nets were doubled, or trebled, and put on in this way, they would be the more effectual a screen, as the meshes or openings would, in that case, be rendered very small." Woollen nets are deemed the best, and are now in general use in Scotland. Bass nets are used in Sweden, and straw nets at the Duke of Buccleugh's garden at Dalkeith. "In screening with nets of any kind," Nicol observes, "they are always to be let remain on night and day, till all danger of frost is past; the trouble of putting them properly on being considerable, and there being no necessity for repeating such trouble, as they will in nowise injure the health of the trees, being incapable of shading them very much."

2212. Protecting by canvas or bunting screens is effected either by placing moveable canvas cases over or around detached trees; portable hand-cases over herbaceous plants; tents or open sheds over the florists' productions; or frames or sheets against trees trained on walls. In all cases they should be placed clear of the tree or plant, either by extended, forked, or hooked sticks, or hooping, or any other obvious resource. "For hot-walls," Nicol observes, "they should be placed about the distance of a foot at top, and of eighteen inches at bottom. In using canvas or bunting screens, in either of the above-menioned forms, the trees are always to be exposed to the free air and light, in good weather, through the day; screening only at night, and on bad days; applying them from the time the buds begin to open, till the fruit is fairly set, or till any fear of further danger from the effects of frost be past."

2213. Protecting by mats is the commonest of all modes for bushes, beds, and single herbaceous plants. Sometimes also screens of mats sewed together, or bound in frames, are applied to fruit-trees, either singly or in frames, or on hooks and pegs. Nicol considers that they are "in no way so good, effectual, or ultimately so cheap screens as those of canvas."

2214. Protecting by straw and litter is effected in herbaceous plants by laying it round their roots, as in the artichoke, asparagus, &c.; or covering the tops of seedlings, which was formerly done, in cultivating the cucumber and melon, and is still practised by market-gardeners in raising radishes and other tender salading. Straw is also formed into coverings of various sorts for frames; screens for projecting from walls; and cones for bushes, herbaceous plants, and bee-hives.

2215. Protecting by oiled paper frames is effected on exactly the same plan and principle as that by bunting or canvas screens. "Frames covered with oiled paper have been successfully employed at Grangemuir garden in Fifeshire. The frames are of wood, inch and half square, with cross bars mortised into the sides. To give support to the paper, strong packthread is passed over the interstices of the frames, forming meshes about nine inches square. Common printing (or unsized) paper is then pasted on; and when this is quite dry, a coating of boiled linseed-oil is laid on both sides of the paper with a painter's brush. These frames are placed in front of the trees, and made moveable, by contrivances which must vary according to circumstances. If the slope from the wall be considerable, a few triangular side frames may be made to fit the spaces. At Grangemuir, the frames are not put up till the blossoms be pretty well expanded; till which time they are not very apt to suffer from spring frosts or hail showers. In this way, it may be remarked, there is much less danger of rendering the blossom delicate by the covering, than if they were applied at an earlier period. The paper frames, if carefully preserved when not in use, will endure for a good many years, with very slight repairs."

2216. Protecting copings and horizontal shelters, mentioned by Miller and Laurence, are used chiefly with a view of preventing the perpendicular cold. They are projected generally from the top, but in lofty walls, also from the middle, and remain on night and day during the cold season. When there is only a temporary coping, it is recommended by Miller and others to be hinged, and to have strings hanging down from
every board on each side of the wall, so as the board may be projected or thrown back to rest on the top of the wall at pleasure.

2217. Protecting by transparent covers is effected with small plants by placing over them a hand or bell glass; with larger ones, by other portable bell or curvilinear shaped portable cases, and with considerable shrubs or fruit-trees by movable cases or glass tents. (fig. 226.) For culinary seedlings, herbaceous plants in pots, and young trees of delicate sorts, timber frames with glass covers are used; or the plants are placed in pits dug in the ground, over which sashes are laid. In whichever way transparent protections are used, they must be partially or wholly removed, or otherwise opened, in fine weather, to admit a change of atmosphere, and a free current to dry up and destroy the appearance of what are called damps; and also to harden and prepare such plants for the removal of the covers.

2218. Transparent screens are made by placing sashes not in use on edge, and thus forming as it were glass walls or partitions, which, applied to green-house plants, set out in the open air, have the effect of producing shelter without shade, and at the same time of admitting the fall of rain on the plants. Many plants receive sufficient protection by being placed near to the south side of a wall, hot-house, or other building, or under a tree or bush during the winter months, without any covering or guard whatever.

Sect. VIII. Operations relative to Vermin, Diseases, and other Casualties of Plants and Gardens.

2219. The casualties of gardens, from human enemies, vermin, and diseases, are numerous, and have given rise to a variety of devices and operations.

Subsect. I. Of the Kinds of Vermin most injurious to Gardens.

2220. The human enemies of gardens are such as break in secretly to steal clandestinely, to injure, or destroy; or, under the guise of regular operators, pilfer and otherwise act as enemies to the garden and its proprietor. The operations for deterring and detecting thieves are, watching by men, by dogs, by peacocks and turkeys allowed to sit on high trees, and by ducks. The dog is most effectual; but peacocks and ducks are known to scream or cry on the approach of strangers in the night-time; as neither of these birds scratch the earth, they are in some descriptions of gardens, especially nurseries, more useful in picking up insects than they are injurious. Man-traps, spring-guns, and alarums, are also set to detect and deter, and the notices of these dreadful instruments, as well as the fear of the law, have considerable influence.

2221. The brute vermin which injure gardens and garden-productions may be classed as quadrupeds, birds, insects, and worms.

2222. Of the quadruped enemies, the larger are excluded by fences, and the smaller species which are most injurious are, the hare, mouse, mole, and rat. Where the hare or other similar animals are not excluded by a sufficient fence, they must be caught by traps or shot. Or where the hare is chiefly injurious by barking trees, smearing the stem with cow-dung, ordure, tar, or coal-liquor will deter them. Mice may be kept under by the different domestic traps, or the gardeners' or fourth figure trap, or by an earthen vessel with a narrow mouth and belled out within, sunk in the earth, and a few leaves or straws placed over it, as is common about Paris. But two or three cats kept in a garden, are the most effectual destroyers of mice. The mode of setting the common moletrap is familiar to every countryman; the true mode however of getting rid of moles, and one most readily put into execution is, to dig up their nests in spring. The heaps of earth over these nests are easily known from common mole-heaps by their size. Field rats are destroyed by dogs; and house rats, where they are troublesome, by poison and other well known means.

2223. The feathered enemies of gardens are numerous but not very destructive, excepting in very severe winters, when they eat the buds, and during the coming up of small seeds. To preserve ripening or germinating seeds where birds are numerous, they must either be covered with a net or watched by man. Scares of different sorts, as mock men or cats, mock hawks or eagles, miniature windmills, rattles, lines with feathers, the smell of tar and bruised gunpowder, &c. are of some use; but the chief dependence must be on watching, nets, and the frequent use of the gun. P. Musgrave, a practical gardener, who has treated the subject of vermin in a scientific manner, has the following observation on this subject. "It is a too common practice amongst gardeners to destroy without discrimination, the birds which frequent their gardens. This, in my opinion, is bad policy. Although I am aware some of the kinds of birds are great enemies to some crops, it certainly must be a trifling crop indeed, that will not bear the expense of a person to watch it, or a net to protect it, until it is out of danger: thus the gardener preserves the birds to perform a double office,—eating up the vermin from the trees, and the seeds of weeds and eggs of insects from the ground. I have often stood and observed the male bird, while the female was sitting upon her eggs or her young, fly to the spot with his bill full of caterpillars to feed his mate or young; and when the young ones become so strong as to
accompany their parents in quest of food, it is really astonishing the number of caterpillars they destroy. I can say, from my own observation, that if it was not the case that the birds destroy a vast number of caterpillars, our trees in general would exhibit nothing but bare stumps, for the insects would become as numerous as the locusts of Spain and America. It is from that circumstance that we find so few flies in comparison of the great number of caterpillars. I one day followed a nest of young ox-eyes, which had just flown, in order to see how the old ones acted. I saw them fly from branch to branch, and pick from the curled leaves the caterpillars, with which they flew to their young to feed them. From these considerations, it is my opinion, that should the gardener, instead of pursuing a system of indiscriminate warfare against the feathered tribe, avail himself of the services of these useful allies, he might, with their exertions and his own united, soon rid himself of those insects that have hitherto set his efforts at defiance.” (Cal. Mem. iii. 333.)

2224. The insects which infest plants are almost as numerous as the plants themselves: almost every species having a particular insect which it seems destined by nature to support. Insects are distinguished from quadrupeds, birds, and reptiles, by their more numerous feet, being without bones, and by their head being furnished with a pair of antennae or horns. From the vermes, or worm-like animals, insects are sufficiently distinguished by their having feet.

2225. Taking a general view of insects we find most of them are oviparous; of course the first state in which insects appear is that of an ovum or egg. This relates to the generality of insects, for there are some examples of viviparous insects, as in the genera aphis, musca, &c. The eggs of insects (fig. 393.) are of two sorts: the first membranaceous, like the eggs of the tortoise, and the other reptiles; the other covered with a shell like those of the birds. Their figure varies exceedingly; some are round, some elliptical, some lenticular, some cylindrical, some pyramidal, some flat, some square, but the round and oval are the most common. As an example of the various shapes of the eggs of insects, and of their natural as well as magnified size, we refer to those of the common slug (a), phalena nupta (b), brown-tailed moth (c), currant-moth (d), common gooseberry-moth (e), turnip-butterfly (f), spider (g), house-cricket (h), and common chafer (i).

2226. The eggs of insects seldom increase in size, from the time they have been deposited by the parent, till they are hatched; those of the tenthredo, however, and of some others, are observed to increase in bulk. At first there is nothing to be perceived in the eggs of insects but a watery fluid; after some little time, the head, like an obscure point, is observable in the centre. The little insect remains in the egg till its limbs have acquired strength to break the egg and make its escape; the different species of insects remain enclosed in the egg for very different periods; some continue encased only a few days, others remain for several months. The eggs of many insects remain without being hatched during the whole winter, and the young insects do not come forth from them, till the season at which the leaves of the vegetables on which they feed begin to expand.

2227. The insect in its second or caterpillar state (fig. 394.) has been usually known by the name of eruc or larva, being a sort of masked form or disguise of the insect in its complete state. The larvae of insects differ very much from each other, according to the several tribes to which they belong; those of the butterfly (Papilio) and moth (Phalaena) tribes are generally known by the name of caterpillars; those of the beetle (Scarabeus), except
such as inhabit the water, are of a thick, clumsy form, called grubs. The larvae of the locust, or grasshopper (Gryllus), do not differ very much in appearance from the complete insect; except being without wings. The larvae of flies (Musca), bees (Apis), &c. are generally known by the name of maggots, and are of a thick short form. Those of water-beetles (Dytiscus) are of highly singular forms, and differ, perhaps, more from that of the complete insect than any other, except those of the butterfly tribe. Some insects undergo no change of shape, but are hatched from the egg complete in all their parts, and they undergo no farther alteration than that of casting their skin from time to time, till they acquire the complete resemblance of the parent animal. In the larva state most insects are peculiarly voracious, as in many of the common caterpillars. In their perfect state some insects, as butterflies, are satisfied with the lightest nutriment, while others devour animal and vegetable substances with a considerable degree of avidity. As an example of the caterpillar state of some of the commoner insects, we may refer to that of the privet-moth (Sphinx ligustri) (a); the cabbage-butterfly (Papilio brassica) (b); the turnip-butterfly (P. napi) (c); gooseberry-moth (Phalaena wavaria) (d); the currant-moth (Ph. grossularia) (e); the dragon-fly (Libellula virgo) (f); the common chafer (Scaeva melolontha) (g); the phryganea rhombica (h); the frog-hopper (Cicada spumaria) (i); and the musca pumilionis (k).

2228. When the larva is about to change into the chrysalis or pupa state (fig. 395) it ceases to feed, and having placed itself in some quiet situation, lies still for several hours, and then, by a sort of effort, it divests itself of its external skin, and immediately appears in the different form of a chrysalis or pupa; in this state, likewise, the insects of different genera differ almost as much as the larva. In most of the beetle tribe it is furnished with short legs, capable of some degree of motion, though very rarely exerted. In the butterfly tribe it is destitute of legs; but in the locust tribe it differs very little from the perfect insect, except in not having the wings complete. In most of the fly tribe it is perfectly oval, without any apparent motion or distinction of parts. The pupa of the bee is not so shapeless as that of flies, exhibiting the faint appearance of limbs. Those of the dragon-fly (Libellula) differ most widely from the appearance of the complete insect; from the pupa emerges the image or insect in its ultimate form, from which it never changes, nor receives any farther increase of growth. As examples of the chrysalis of various insects, we give those of the beetle (Scaeva melolontha) (fig. 395. a), papilio napi (b), P. Io, (c), phalaena grossularia (d), Ph. wavaria (e), tipula cornicina (f), phryganea rhombica (g), musca pumilionis, natural size and magnified (h, k).

2229. The sexes of insects are commonly two, male and female. Neuters are to be met with among those insects which live in swarms, such as ants, bees, &c. As examples of the appearance of different insects in regard to sex, we refer to the male, female, and neuter ant (fig. 396. a, b, c), and to the male or drone, female or queen, and neuter or working bee (d, e, f).

2230. In duration, the majority of insects are observed to be annual, finishing the whole term of their lives in the space of a year or less, and many do not live half that time; nay, there are some which do not survive many hours; but this latter period is to be understood only of the animals when in their complete or ultimate form, for the larvae of such as are of this short duration have in reality lived a very long time under water, of which they are natives; and it is observed, that water insects in general are of longer duration than land insects. Some few insects, however, in their complete state, are supposed to live a considerable time, as bees for instance; and it is well known that some of the butterfly tribe, though the major part perish before winter, will yet survive that season in a state of torpidity, and again
appear and fly abroad in the succeeding spring; spiders are also thought to live a considerable time.

2231. The arrangement of insects, according to the Linnean system, is divided into seven orders. The natural orders and families into which they have been divided by subsequent naturalists are very numerous; and therefore, we shall notice only the artificial orders of Linnaeus, viz. 1. Coleoptera; 2. Hemiptera; 3. Lepidoptera; 4. Neuroptera; 5. Hymenoptera; 6. Diptera; and 7. Aptera. The leading characters of these orders, and the names of the genera belonging to them which are most noxious to plants in a state of culture, will be of some use in enabling the gardener to use a correct nomenclature, as well as to enlighten him generally on the intricate and little understood subject of insects.

2232. The coleoptera have a hollow horny case, under which the wings are folded when not in use. The principal genera are — 1. Scarabaeus (beetles); 2. Lucanus (stag-beetle); 3. Dermestes; 4. Coccinella (lady-bird); 5. Curculio (weevil); 6. Lampyris (glow-worm); 7. Meloe (Spanish fly); 8. Staphylinus; 9. Forficula (earwig). Like other winged insects, all the beetles live for some time in the form of caterpillars, or grubs. The caterpillars of the garden-beetle, cockchafer, &c. lead a solitary life under ground, and consume the roots of plants; those of others feed upon putrid carcases, every kind of flesh, dried skins, rotten wood, dung, and the small insects called pucerons, or vine-fretters. But after their transformation into flies, many of the same animals, which formerly fed upon dung and putrid carcases, are nourished by the purest nectaraceous juices extracted from fruits and flowers. The creatures themselves, with regard to what may be termed individual animation, have suffered no alteration. But the fabric of their bodies, their instruments of motion, and the organs by which they take their food, are materially changed. This change of structure, though the animals retain their identity, produces the greatest diversity in their manners, their economy, and the powers of their bodies. The beetles (fig. 397.) produced in the palm called the mountain cabbage-tree (Areca) has a grub or caterpillar (fig. 398.) the size of a man’s thumb, extremely fat; “fried with butter or salt, or spitted on a wooden skewer, they are esteemed excellent. In taste they partake of all the spices of India, as mace, cinnamon, cloves, nutmegs, &c. Several species are produced in all the palm-trees when beginning to rot, some larger than others, all of a pale yellow color with black heads.” (Stedman’s Surinam.)

2233. Of beetles the scarabaeus melolontha (fig. 399. a) is the most common. The eggs are deposited in the ground by the parent insect, whose fore legs are very short, and well calculated for burrowing. From each of these eggs proceeds, after a short time, a larva with six legs, a red head, and strong claws, which is destined to live in the earth under that form for four years, and then undergoes various changes of its skin, until it assumes its chrysalid form. These creatures, sometimes in immense numbers, work between the turf and the soil in the richest meadows, devouring the roots of the grass to such a degree that the turf rises, and will roll up with almost as much ease as if it had been cut with a turfing-knife; and underneath, the soil appears turned into a soft mould for above an inch in depth, like the bed of a garden. In this the grubs lie, in a curved position, on their backs, the head and tail turned, and the rest of the body buried in the mould. Such are the devastations committed by the grubs of the cockchafer, that a whole field of fine flourishing grass, in the summer time, become in a few weeks withered, dry, and as brittle as hay, by these grubs devouring the roots, and gnawing away all those fibres that fastened it to the ground, and through which alone it could receive nourishment. The larvae having continued four years in the ground, are now about to undergo their next change: to effect this, they dig deep into the earth, some forming a smooth case, in which they change into a pupa or chrysalis. They remain under this form all the winter, until the month of February, when they become perfect beetles; but with their bodies quite soft and white. In May the parts are hardened, and then they come forth out of the earth. This accounts for our often finding the perfect insects in the ground. The most efficacious mode of preventing their increase is to employ proper persons to take the flies in May and June, before they have laid their eggs; which, though it appears an endless task, may be done with very considerable effect, by shaking and beating the trees and hedges in the middle of the day. Children will be able to do this; and, as has been proved by experiment, will, for a trifling reward (suppose a penny a hundred), be glad to form a single village. Domestic fowls of all kinds are particularly fond of these beetles, so that the expense of collecting them would be fully compensated by the quantity of food they would afford in this way. When land is ploughed up in the spring, if the weather be very wet, the grubs are set, in which case, rocks, gulls, and jays will be sure to detect and destroy them. These birds, therefore, should not be driven away, as the occasional damage they commit is amply repaid by their unceasing exertions to destroy various insects. The almost sole employment of rooks, for three months in the spring, is to search for this sort of food, and the havoc that a numerous flock makes amongst them must be very great.

2234. The lady-bird (Coccinella) feeds chiefly on aphides, and therefore is not considered as injurious to gardens. The weevil (Curculio) is a very numerous and splendid genus; the larvae of some infest granaries, others may be found inside of artichokes and thistle-flowers. All the species feed on the seeds or leaves of vegetables. One of the most common is the nut-weevil (C. mucron) (fig. 399. b), of which the larve (c) and pupa (d)
are both nearly of the size of the perfect insect. To this genus also belongs the insect generally known by the name of diamond beetle.

2238. _Dytiscus, Hydrophilus_ are aquatic genera, inhabitants of ponds and stagnant waters, they swim with great dexterity; their hind legs are particularly fitted for their residence in the water, being thin and flat, and having the inner edges furnished with stiff hair-like appendages which act as fins or oars; the antennæ are furnished with long hairs, by means of which, in walking on the surface of the eggs, the setting on of the feet. The larvae (as is common with aquatic insects) remain a long time in the imperfect state, some two to four years; they secrete themselves in holes in banks, and devour other insects, worms, and the young fry of fish, which they destroy by sucking out their juices.

2239. The earwig (Forficula) frequents moist ground, is very injurious to flowers and fruit, and may easily be taken by suspending any hollow article on a plant or twig, as it retires in the daytime to such retreats, and feeds mostly during the night.

2238. The hemiptera are all furnished with wing-coverings of a softer texture than the coleoptera; these covers do not meet in a direct line as in that order, but the base of the left wing covers the inner margin of the right; in some, the wings nearly cross at the tips; the mouth is either situated on the breast, or inclining towards it. The principal genera are—1. Blatta (cockroach); 2. Gryllus (locust, grasshopper); 3. Fulgora (lantern-fly); 4. Cimex (bug, &c.)

2239. Of the cock-roach (Blatta) many species are exceedingly injurious, devouring most kinds of provisions, paper, leather, and vegetable substances; they are generally nocturnal insects, and are found in great abundance in bakehouses, and other warm places. They are all killed without any external injury, by immersion in boiling water.

2240. The black cock-roach, improperly called the black beetle (B. orientalis) (fig. 404.), was originally a native of South America, but is now very generally spread throughout Europe. It cannot be considered a British insect, though it frequents kitchens, ovens, and warm places, and devours meal, bread, and other provisions, shoes, &c. It conceals itself during the day, and comes abroad in the night; it runs quickly, and is very tenacious of life. They are killed by red wafers. The egg (a) is of a considerable size, and the pupa (b) larger than the perfect insect (c).

2241. The gryllus genus comprehends a number of species, some of which are called grasshoppers, others locusts, and others crickets. The caterpillars of the gryllae have a great resemblance to the perfect insects, and, in general, live underground. Many of these insects feed upon the leaves of plants; others, which live in houses, prefer bread and every kind of farinaceous substance.

The house-cricket (G. domestica) (fig. 401. a) is one of the busiest little insects that reside altogether in our dwellings, and intrude themselves on our notice, whether we wish it or not. They are partial to houses newly built, for the softness of the mortar enables them to form their retreats, without much difficulty, between the joints of the masonry, and immediately to open communications with the different rooms. They are particularly attached to kitchens and bakehouses, as affording them a constant warmth. In some of the warmer countries, this genus of insects is, of all the pests that mankind are subject to, the most injurious, destroying vegetables of every kind and even from their numbers alone, constituting one of the heaviest afflictions that can happen to a country. The mischiefs done by the blatte, or cock-roaches, is trifling, compared with those of this destroying tribe, for the dreadful ravages committed by the locusts are such as to reduce the most fertile fields to the appearance of barren deserts; they devour the fruits, leaves, and even the buds and bark of trees, and have even been known to devour reeds used in thatching the human habitations, so unfortunate as to be visited by these devouring hordes. Jackson depicts their ravages in the empire of Morocco, and gives a figure of the insect (fig. 402.) of half the natural size. In Abyssinia, China, and other countries, the caterpillar or larva of certain species of roaches and locusts is, like that of some beetles (2238.), eaten by the natives.

The hopper, or cow-crick insect (Cicada) feeds, on various kinds of plants; the grub or larva is without wings; in the pupa the wings are very short; but in both states they are exceedingly active. The males are distinguished by their loud chirping note, the females are quite mute. In the fly state, they are found on the leaves and stems of plants, and in the immature state about the roots of grass and trees. The white froth-like spittle, which is seen on the leaves and stalks of many kinds of plants in the summer season, is produced by the black-headed frog-hopper (Cicada spumaria) (fig. 401. b), and if this froth be wiped off and examined, will be found to contain the larva young of the cicada: and this matter, which is discharged from its own body, no doubt serves to protect it from the attacks of other insects.

2242. The plant-louse, vine-tetter, or puceron, (Aphis) is a very common insect, the numerous species being denominated from the trees and plants which they infest. The males are winged, and the females without wings; they are viviparous producing their young alive in the spring; and also oviparous, lay.
ing eggs in the autumn. As these insects derive their nourishment from the juices of the plants which they infest, nature has wisely ordained that the females should lay eggs in the autumn, though they themselves do not hibernate. This is to prevent their being starved for the want of food in winter. The young burst forth from their eggs in spring as soon as there are leaves to subsist upon. Their noxious effects are well known to the gardener. They sometimes migrate, and suddenly fall in showers on spots that were until then free from their ravages. Water drenched with lime-water will prove as destructive to them as any thing when on trees; and smaller plants may be washed with lime-water, with elder-leaves infused in water, or with common soap-suds, any of which will destroy the insects. The larvae of the lady-bird eat thousands of aphides, and some ants also devour them; and some plants are infested with aphides which would probably prove serviceable to scatter ants, which may always be procured in abundance, upon infested trees. The aphides sometimes settle upon the tops of beans, covering them so thickly as to make them appear quite black: in such cases the crops may often be preserved by cutting off the tops, a practice which is likewise adopted independently of this for the purpose of increasing the yield of beans. (Dr. Skirnsmiile’s Essay Intro. to Nat. Hist., vol. i. p. 149.)

2243. The chermes (fig. 401, c, d, e) is a genus very generally confounded with aphids; it also inhabits the leaves and stems of plants, and by its punctures, produces excrecences and protruberances of various sizes and shapes, which are generally found to enclose either the egg or immature insect, in the larva stage. There are six, four, and two wings; and the grubs are two, four, and six prolegs, the thorax, which are therudiments of the future wings. The winged insects (c) leap or spring with great agility, and infest a number of different trees and plants: the females (d), by means of a tube at the termination of their bodies, insert their eggs under the surface of the leaves; and the worms, when hatched, give the leaves a very brownish appearance, the leaf, and muscles, and other trees, are sometimes almost entirely covered. The old females, before depositing their eggs, expand to a comparatively large size (e).

2244. The thrips (fig. 401, f) genus consists of very small insects, found chiefly on the flowers of plants, and, excepting when very numerous, are not very detrimental. The natural size is very minute, and therefore to search for this insect the gardener should use a magnifying glass.

2245. Of the cochineal or coccus genus (fig. 401, g) there are several species very injurious in gardens, the pest of which is very well known to gardeners, and by the name of manjil, is found in hot-houses. The males are active, but the females are very inert, being generally fixed to different parts of the plants. The eggs, of their natural size, are mere dots, magnified (g) they appear of an oval shape; the larva is proportionally small, but magnified (h) is oblong and roundish; the males (i) only have wings, and when they form (k) the female is imbedded in a brown male, which, when hatching, becomes enveloped in a case of wool (m). Brushing off these creatures is the only effectual remedy, and, if set about at once and persevered in, will save the trouble of many prescribed washes and powders, which are mere palliatives.

2246. The lepidoptera contains the butterfly, moth, and hawk-moth; they have all four wings covered with scales or a sort of farina; they have a mouth, with palpi, a spiral tongue; the body covered with hair. The scales resemble feathers; they lie over one another in an imbricated manner, the shaft towards the body of the insect, and the expansion toward the end of the wing, reflecting the most brilliant colors.

2247. Of the butterfly genus (Papilio, L.) many thousand species are known in Europe, and in England alone more than ten hundred have been collected by a celebrated entomologist.

2248. The larva, or young, of the different kinds of butterflies and moths, when in that state in which they have just bunched up in buds, which have the leaves of vegetables, and increase in size. They cast their skins occasionally, and sometimes change in color and markings, but never in their general appearance or in their habits. Eating seems to be their sole employment; and when they meet with food that suits their palate, they are extremely voracious, committing great havoc in gardens. But the same cause which restrains the depredations of the aphides and other insects has also set bounds to the destruction occasioned by the caterpillar, who has myriads of internal as well as external enemies. Many flies deposit their eggs in the bodies of caterpillars. From these proceed small maggots, which gradually devour the vitals of the animal in which they reside. When about to change, they cast the skin of the caterpillar, and remain for a while upon the empty skin till they assume the form of flies, and escape into the air to perform the same cruel office to another unfortunate larva. Every person must recollect to have seen the colewort or cabbage caterpillar, or country-cotters, covered with pale green scales, which have the form of small maggots, and are of a fine yellow color. One of the most formidable enemies of the caterpillar is a black worm, with six crustaceous legs: it is longer and thicker than an ordinary-sized caterpillar. In the fore part of the head it has two curved pincers, with which it quickly pierces the belly of a caterpillar, and never quits the prey till it is entirely devoured. The largest caterpillar is not sufficient to nourish this larva for a single day; for it daily kills and eats several of these. These gluttons, when gorged with food, become inactive, and almost motionless; when in this satiated condition, they make a few leaps, and devour the leaves of trees, but perhaps furnish the greatest number of different caterpillars, as well as of different insects. Among others, the oak is inhabited by a large and beautiful beetle. This beetle frequents the oak, probably because that tree is inhabited by the greatest number of caterpillars. It marches from branch to branch, and, when disposed for feeding, that caterpillar that comes in its way.

2249. Chrysalis state. When full grown, the caterpillar seeks some retreat, to prepare for an important change, viz. from the soft caterpillar, possessing motion and feeding so voraciously, to the hard chrysalis, fixed immovably, and sustained without food. The retreat that is chosen and the preparation that is made for this important change vary essentially in different species; some retire to the sheltered situations of houses, walls, and other buildings; some bury themselves in the ground; some wrap themselves up in leaves; others attach themselves to the stalks of plants; while others again eat into the stems of vegetables, or the very heart of trees, and there undergo their metamorphosis. Although each kind of caterpillar seeks a different retreat, yet all of the same species seek the same, and adopt the same means of preservation.
Such as are to lie dormant all winter, seek the warmth of our houses, or dig their way into the ground, behind the expectation of spring. Such as are to leave their prions in a few weeks, and before the end of summer, roll themselves up in the leaves of those plants on which they fed. No caterpillar that is to remain in the state of a chrysalis till the following summer, attaches itself to an annual plant; and none that is to enter on its winged state in winter (which some few do) is ever found but upon evergreen trees. In the preservation of the edibility of their metamorphosis, caterpillars differ as much as in their selection of a proper place. Some attach themselves by a thread from their tails, and are suspended perpendicular; while others, among which is the white cabbage butterfly, by another thread across the body. The species of the snail are silk-worm and several others spin a complete covering or case for their bodies, some of finer materials and less agglutinated together than others. Some caterpillars form a ball or nest of the mould in which they are buried, glued together by their saliva, and smoothed within; and others fasten two leaves together, or, curving its edges, unite two parts of the same leaf by threads and bands, and thus form a covering for themselves.

2290. Perfect insect. After the animal has lain dormant its due time in the chrysalis state, the skin or shell bursts, and the perfect insect, in its winged state, creeps out, gradually expands its wings, and, when these are expanded, emerges from a gap left in the side of the air. It now no longer seeks to satisfy its hunger on the food that it devoured when a caterpillar, but sips the nectar from the blossoms of the flowers. Having fulfilled the intentions of nature, they deposit their eggs with care, and, having thus provided for a future generation, the insect terminates its short but brilliant career. In the deposition of their eggs, the eggs of the moth differ from those of the wonderful instinct in selecting precisely such places as are best adapted to their future young; such plants, for instance, as will furnish food for the new-born caterpillars, and such parts of plants as are not likely to be removed by decay, or such as will be exactly in their way, around which the caterpillars are to be born. Thus, a little insect (Tinea ponousa) lays its eggs in the blossom, that its caterpillar may feed on the fruit of the apple; and several others act in the same provident way.

2291. The most remarkable British butterflies are—the purple emperor (Papilio iris), which appears in July, and is considered the most beautiful; the peacock butterfly (P. Io), whose wings are of a brownish-red color with black spots, is sufficiently common in the south of England, but extremely rare in the north; the tortoiseshell butterfly (P. urticae) (fig. 403.), which appears in its winged state about the month of April, is one of the most common, and at the same time the most beautiful of the British lepidoptera; the upper wings are red, and marked with alternate bands of black and pale orange; the eggs (a), caterpillar (b), and chrysalis (c) are each elegant in their kind. The magadine blue butterfly (P. cyamus) is also an admired species.

2292. The hawk-moth, sphynx, or sphinx, is chiefly seen in the evening. The name sphynx is applied to the genus on account of the posture assumed by the larva of several of the larger species, which are often seen in an attitude much resembling that of the Egyptian sphynx, with the four parts elevated, and the rear end applied flat to the floor. One of the most elegant insects of this genus is the privet

403.

The hawk-moth (Sphinx ligustri) (fig. 404.), measuring nearly four inches and a half from wing end to wing end, which is very large, is smooth, and of a fine green, with seven oblique purple and white stripes along each side: at the extremity of the body, or top of the last joint, is a horn-shaped protuberance, which is downward. This beautiful caterpillar is often found in the months of July and August, feeding on the privet, the lilac, the poplar, and other trees, and generally changes to a chrysalis (fig. 404. a) in August or September, retiring for that purpose to a considerable depth beneath the surface of the ground; and after casting its skin, continuing during the whole winter in a dormant state, the sphinx emerging from it in the succeeding June. The egg of the sphinx (b) is very different from that of the papilio. Another perhaps still more beautiful insect is the sphinx ocellata, or eyed hawk-moth, which is principally found on the willow-tree, in its perfect state, in the month of June. The largest and most remarkable of the British hawk-moths, is the sphinx atropos, or death's head hawk-moth. The upper wings are of a fine dark-grey color, with a few slight variegations of dull orange and white: the under wings are of a bright orange color, marked by a pair of transverse black bands: the body is also orange-colored, with the sides marked by black bars: on the top of the thorax is a very large patch of a most singular appearance, exactly resembling the usual figure of a skull, or death's head, and is of a pale grey, varied with dull ochre color and black. When in the least disturbed or irritated, this insect emits a most appallingly loud sound, sometimes like the squeaking of a bat or mouse; and from this circumstance, as well as from the mark already mentioned, it is held in much dread by the vulgar in several parts of Europe, its appearance being regarded as a kind of ill omen, or harbinger of approaching fate. The caterpillar from which this curious sphinx proceeds, which is principally found on the potato and the jessamine, is in the highest degree repulsive, measuring sometimes five inches in length: its color is a bright yellow, and its sides are marked by stripes of a mixed violet and sky-blue color. It usually changes into a chrysalis in the month of September, and emerges the complete insect in June or July following: some individuals, however, change in July or August, and produce the moth in November.
2253. **The moths (Phalanae)** are a numerous genus like the sphinges. They fly abroad only in the evening and during the night, and obtain their food from the nectar of flowers. The larva is active and quick in motion, and preys voraciously on the leaves of plants. The most remarkable British moths are the **clothes-moth (P. sartorius)** (fig. 405. a); the eggs of which are deposited on woollen clothes, furs, &c. on which the larve feed and change to chrysalids, appearing in the imago state in August. The most troublesome in gardens are the cabbage-moth (P. oleaena) (b), the gooseberry-moth (P. nervaria) (c), the currant-moth (P. granularia) (d), and the cooling-moth, common on fruit-trees, hedges, and oak-trees (P. pomonella) (e).

2254. **The neuroptera**, or nerve-winged insects, have four naked membranaceous wings, but no stings; and they differ from the last order, as their wings are without their minute scales or down. Most of the insects in this family are aquatic, residing in the water during their immature state, and resorting thereto in their perfect state.

2255. **The dragon-fly (Libellula)** is well known as frequenting rivers, lakes, pools, and stagnating waters, in which the females deposit their eggs. The egg, when deposited by the parent in the water, sinks to the bottom, and remains there till the young insect has acquired sufficient maturity and strength to burst from its confinement. The larva, at first small, increases to nearly half the size of the perfect fly, by changing its state at different intervals, the caterpillars of moths and butterflies. The slender-bodied dragon-fly (L. virgo) (fig. 405. a) is the most common.

2256. **The day-fly (Ephemerata)** differs in many respects from all other insects. The larve live in water (where earth and clay seem to be their only nourishment) for three years, the time they consume in preparing for their change, which is performed in a few moments. The larva, when ready to quit that state, rises to the surface of the water, and, getting instantaneously rid of its skin, becomes a chrysalis. This chrysalis is furnished with wings, which it makes use of to fly to the nearest tree or wall; and there settling, it in the same moment quits a second skin, and becomes a perfect ephemera. In this state all the species live but a very short time, some of them scarcely half an hour, having no other business to perform than that of continuing the race. They are called the insects of a day; but very few of them ever see the light of the sun, being produced after sunset, during the short nights of summer, and dying long before the dawn. All their enjoyments, therefore, excepting coition, are confined to their larva state. The E. vulgaris (fig. 406. b) is the largest British species.

2257. **The spring-fly (Phryganea)** in the caterpillar state, lives in the water, and is covered with a silken tube. The caterpillars or larve have a very singular aspect; for, by means of a gluten, they attach to the tubes in which they are enclosed small pieces of wood, sand, gravel, leaves of plants, and not unfrequently live on testaceous animals, all of which they drag along with them. They are very commonly found on the leaves of the water-cress; and, as they are often entirely covered with them, they have the appearance of animal plants. They are in great request among fishermen, by whom they are distinguished by the name of stone or cod-bait. The fly, or perfect insect, frequents running water, in which the females deposit their eggs. P. rhombica (fig. 406. c) is common.

2258. **The hymenoptera**, or four-winged insects with stings, includes the gall-insect, wasp, bee, ant, &c. At the extremity of the abdomen, the females of several of the ge-
nera have an aculeus or sting, that lies concealed within the abdomen, which is used as a weapon, and instills into the wound an acrid poison: those which want the sting are furnished with an oviduct that is often serrated, and with which the eggs are deposited, either in the bodies of the caterpillars of other insects, or in wood. From these eggs the larvae are produced, which in some have no feet, in others more than sixteen. They change to pupa incompleta, which are enclosed in cases. Some of the insects of this order live in societies, others are solitary.

259. The gall-fly (Cynips) pierces the leaves, &c. of plants with its sting, and deposits its eggs in the wound; the extravasated juices rise round it, and form a gall (fig. 407. a) which becomes hard; and in this the female feeds, and changes to a pupa, (c, e), and afterwards to the imago, or perfect insect (d).

The C. quercus folii (fig. 407. d), and C. glechomatis, or ground-ivy gall-fly, are very common.

260. The saw-fly (Tenthredo), in the larva state (fig. 407. e), bears a strong resemblance to some of the caterpillars of the lepidopterous insects; but is distinguishable by the number of the feet, which are never fewer than sixteen, exclusive of the thoracic pairs; the larve feed on the leaves of plants, and the pupa is enclosed in a strong gumy case (f), retiring in the autumn, and the perfect fly (g) emerges early in the ensuing spring. The serated sting is used by the female in the manner of a saw, to make incisions in the twigs, or stems of plants, where it deposits its eggs. T. rose (fig. 407. c, f, g) is a common species. The T. grossularian (h) is also frequent in gardens: both are very troublesome species of this genus.

261. The ichneumon is a very numerous genus, there being upwards of 800 British species. The eggs, in most kinds, are deposited in the bodies of caterpillars or pupae, which are there hatched: the larve have no feet; they are soft and cylindrical, and feed on the substance of the caterpillar; this last continues to feed and even to undergo its change into a chrysalis, but never turns to a perfect insect: when the larve of the ichneumon are fully grown they issue forth, spin themselves a silhy web, and change into a pupa incompleta, and in a few days the fly appears. The I. manifestator (fig. 407. i) is common in woods.

262. The bee (Apis), wasp (Vespula), and ant (Formica) are well known. All the species of ant are of three sorts, male, female, and neuter: the neuters alone labor; they form the ant-hill, bring in the provisions, feed the young, bring them to the air during the day, carry them back at night, defend them against attacks, &c. The females are said to be retained merely for laying eggs, and as soon as that is accomplished they are unmercifully discarded. The males and females perish with the first cold; the neuters lie torpid in their nest, and thus nature compensates them by duration, what it denies them in intensity of enjoyment.

263. The dixena, or two-winged insects, have two wings, and behind or below them two globular bodies, supported on slender pedicles, called halteres or poises. At the mouth they have a proboscis, sometimes contained in a vagina, and sometimes furnished at its sides with two palpi, but no maxilla. Their eyes are reticulated and large. The females, in general, lay eggs, but some are viviparous; the larve of the insects of this order are as various in their appearance as the places in which they are bred. In general they do not cast their skins, but change into a pupa state. Flies, strictly so called, gadflies, and gnats belong to this order.

264. The gad-fly (Estrus) is a genus exceedingly troublesome to horses, cattle, and sheep, in the skins of which they deposit their eggs (fig. 408. a), which soon change into larve, that feed under the skin of living animals (b), and often line the stomachs of horses under the name of bots (Clarke, in Linn. Trans. vol. iii.); the larve are soft, smooth, annulate, without feet, and in most species furnished with hook-like appendages: the chrysalis (c) differs little in form from the larve. The O. bovis (d) infests oxen; O. hamnorroidalis (e), horses; and O. ovis, sheep.

265. The crane-fly (Tipula) resembles the gnat, it feeds on various substances; the larve are without feet, soft and cylindrical; pupa cylindrical, horned; some species reside amongst the roots of aquatic vegetables, others amongst grass; but by far the greater number are aquatic. The perfect flies are found in abundance in the summertime. The T. olens, or long-legs, feeds on the roots of the cabbage; and the T. crocata (fig. 409. a) and other species inhabit meadows, and are common from spring to autumn. The wheat-fly, T. tritici (b), twelve of which have been observed at one time, laying their eggs in a single ear of wheat, would soon become of serious injury to mankind, were not their race kept within due bounds by several natural enemies, particularly the ichneumon tipule. The well-known gagger long-legs, so frequently seen in houses in the autumnal evenings, flying about the flame of the candles and often perishing in the blaze, is the T. rivos (c), one of the larger species of the genus. The eggs of the wheat-}

{g的部分被遗漏，可能是由于文本的断裂或其他原因。}
2266. The fly genus (Musca) presents many curious species. The common flesh-fly (M. vomitoria) (fig. 410.a) deposits its eggs on the meat in our shambles and larders. These eggs (b) speedily become larvae (c), are soon full grown (d), change to the chrysalis state (e), and in a month the fly appears (f). The rapid multiplication of the fly is thus calculated by Louwenhoek. **"**Let us suppose, that in the beginning of June there shall be two flies, a male and a female, and the female shall lay 144 eggs, which eggs, in the beginning of July, shall be changed into flies, one half males and the other half females, each of which females shall lay the like number of eggs; the number of flies will amount to 10,000; and, supposing the generation of them to proceed in like manner another month, their number will then be more than 700,000, all produced from one couple of flies in the space of three months.**"** The Hessian fly (M. ptilotis) (f) is very destructive to wheat and rye, and has occasionally been a source of great alarm to our agriculturists. The cheese-fly (M. putris) (g), well known to housewives under the name of hopper, deposits its eggs in the crevices or holes of the cheese, whence those numerous maggots (h), that so much amuse us by their agility and surprising leaps. One of these insects, not a quarter of an inch in length, has been known to leap out of a box six inches deep. The chrysalis (i) is straight and crasty.

2267. The gnat (Culis) is frequent in the neighborhood of waters and marshy places. In southern regions there is a larger species, which is known by the name of musquito. Its bite is painful, raising a considerable degree of inflammation, and its continuall piping note is exceedingly irksome where it abounds, especially during the night. When it settles to infest the wound and draw the blood, it raises its hind pair of feet. In Lapland, the injuries the inhabitants sustain from it are amply repaid by the vast number of water-fowl and wild-fowl which it attracts, as it forms the favorite food of their young. The fecundity of the common gnat (C. pipiens) (fig. 410. k) is as remarkable as that of the flesh-fly.

2268. The tabanus genus greatly resembles musca, and produces some species troublesome to men and other animals on whose blood they feed. The spider fly (Hippobosca) inhabits woods. The species known as the forest-fly (H. equus) (fig. 410. f) is particularly tormenting to the horse.

2269. The aptera, or insects without wings in both sexes, is composed of genera of such varied forms, that no other general characters can be affixed. Linnaeus comprehended in this order spiders, lice, lobsters, crabs, shrimps, &c. which Leach and most other modern naturalists class separately.

2270. The louse (Pediculus) and flea (Pulex) are well known: the only genera of this order which are troublesome in gardens are the mite-spiders (Acarus), the common spider (Araneus), and the wood-louse (Oniscus).

2271. The red spider is the Acarus telarius, L. (fig. 411.a), and the same name is also applied by gardeners to the scarlet acarus (A. holocyclus, L. (b)), the only two British species of the genus which infest plants, and to which perhaps they do more injury than all other insects put together. Watering over the leaves is the well known preventive and remedy; the water should be applied to both sides of the leaf in a finely divided state, and with great force, so as to dash the insects to the ground. For this purpose Read's syringe is the most efficient implement at present in use. The sheep-tic (A. rediarius) (c), the dog-tic (A. riecius) (d), the cheese-mite (A. sior), and the itch-mite (mite de la galé, Fr.) (A. exulcerans, L) which inhabits the ulcers of the itch, are the principal species mentioned by Linneus; but some naturalists consider that every animal, and most plants, have their peculiar species of acarus. The harvest bug is by some considered an acarus, and by others a phalangium.

2272. The common spider (Araneus) is a numerous genus, and very prolific: as they live entirely on insects they cannot be considered as otherwise injurious in gardens than by their unsightly appearance.

2273. The wood-louse (Oniscus) is of retired habits, shining the light and the heat of the sun. It lives on leaves, fruit, and also on animal substances, and casts its crust or skin like the spider. In gardens it is easily caught by bundles of reeds or beans, or other hollow stalks, like the earwig. The O. aquaticus (fig. c) is common in springs and clear ponds, or estuaries of water. The dog-tic and water oniscus both require to be magnified to be studied properly (f, g).
2274. Of worms (class Vermes, L.), there are only a few genera which are materially injurious in gardens, the earth-worm (Lumbricus), the slug (Limax), and the snail (Helix).

2275. The slug (Limax) is without a shell and distinguished by its lateral pore. There are 16 British species: the L. later (fig. 415, b), alba, and hyalina are the most common in gardens; and the L. agrestis (a) is common both in gardens and fields, and is the species recommended to be swallowed by consumptive persons. The snail (Helix) is a numerous genus, and, like the slug, very destructive to plants and fruit: both snails and slugs are hermaphrodite, having both sexes united in each individual; they lay their eggs with great care in the earth, and the young ones are hatched, the shell without shells formed. They are most troublesome in spring and autumn, and during mild weather in winter. In dry warm weather, and during frosts, they retire into the earth and remain there in a torpid state. The most common species is the H. hortensis (fig. 415, c), or garden-snail, of which it is

remarked, that having once attacked a leaf or fruit, it will not begin on another till the first is wholly eaten. Snails and slugs may be injured by castoric substances scattered over them, or by watering with bitter infusions, acids or alkalis, as vinegar, or what is equally effectual and cheaper, lime-water; but the only effectual way of getting rid of snails in gardens is by hand-picking. They may be collected under decaying leaves or haurian, laid down on purpose to attract them. In this way a garden may soon, and at little trouble and expense, be effectually cleared of the worm class of enemies.

SUBSEC. 2. Operations for subduing Vermin.

2276. The operations for deterring the human, quadruped, and feathered enemies of gardens are few, and have been already noticed. (2220. 2222, 2223.)

2277. The operations for destroying insect vermin, or counteracting their injurious effects, are of three kinds, preventive, palliative, and efficient processes.

2278. The preventive operations are those of the best culture in the most extensive sense of the term, including what relates to choice of seed or plant, soil, situation, and climate. If these are carefully attended to, it will seldom happen that any species of insect will exist in gardens to an injurious degree. But some parts of culture, such as climate, are often beyond our control; as, for example, when a very dry spring and east winds prevail, in which case many insects increase, or rather their larvae are hatched and reared under such favorable circumstances that few of them die, and all of them become strong in proportion as the plants on which they live, in consequence of the dry weather (favorable to the insects), become weak. In such a case as this, or its reverse, that of a series of cold moist weather, the gardener cannot always give good culture to plants in the open air, and therefore cannot prevent the increase of insects. In artificial plant-habitations of every kind, however, properly constructed, his power in regard to culture is complete, and therefore he may always prevent, not the existence, but the injurious increase of insects.

2279. Preventive operations are of the nature of palliative being, and especially animals. Excessive waterings, stormy applications of water with a syringe, violent wind produced by shaking the plant or tree in the air instead of moving the air round the tree, as in natural wind; these and similar operations will materially injure and annoy insects, both in their common functions and in the work of generation, hatching, and rearing. Insects may be further annoyed by throwing on them acidic waters or powders, as tobacco-water, lime-water, powdered quick-lime, soot, ashes, barley-awns, &c. &c. The smell of tar is particularly offensive to various moths and butterflies; and it is said, if a little of it is placed under plants, or if they are watered with tar-water, these insects will not lay their eggs on them. It is also said that if shreds of flannel are hung on trees or plants, moths and butterflies will lay their eggs on the shreds, in preference to the leaves of the plant. The effect of the fumes of tobacco, sulphur, urine, &c. are well known. Saline substances mixed with water are injurious to most insects with tender skins, as the worm and slug; and hot water, where it can be applied without injuring vegetation, is equally, if not more powerfully, injurious. Water heated to 120 or 130 degrees will not injure plants whose leaves are fully expanded and in some degree hardened; and water at 200 degrees or upwards may be poured over leafless plants. There are various other ways in which insects may be annoyed, and often in part destroyed, which will be pointed out in treating of the plants which particular species inhabit. The effects of insects may also be palliated on one species of plant, by presenting to them another which they prefer: thus wasps are said to prefer carrots, the berries of the yew, and the honey of the hova, to grapes, honey or sugared water to ripe fruit, and so on. One insect or animal may also be set to eat another, as ducks for slugs and worms, turkeys for the same purpose, and caterpillars, and ants for aphides, and so on.

2280. The operations for the utter removal or destruction of insects are few, and chiefly that of hand-picking, or otherwise removing or killing by manual operations with a brush, sponge, or net. Destruction by hand-picking should, if possible, commence with the parent insect in its fly or perfect state before it has deposited its ova. Thus the gathering of moths, butterflies, and large wasps may save the gathering afterwards of thousands of caterpillars and the drowning of hundreds of wasps, as preventing seeds from seeding in a garden will soon eradicate them altogether. It is no small proof of the advantages of a knowledge of natural history to gardeners, and also of the progress of knowledge among this ingenious and useful class of artisans, that a practical gardener has actually practiced for several years the catching of moths, to prevent them from laying their eggs on his trees. P. Musgrave, gardener, at May-field near
Edinburgh, has almost completely cleared his trees of caterpillars by the following mode: "I examine," he says, "the trees I wish to clear, in the beginning of June, that being the time the moths begin to leave the chrysalis state. When I find one of those of a dark color, I am aware the insect will make its appearance in my garden. Those which I daily examine, are always capable of doing the greatest mischief. I never see them do not see the insect emerging from the shell, yet I am sure to find it in the neighborhood of the covering which it has left, exhausted with fatigue in consequence of the exertion in extricating itself from confinement. At first I put a few of the chrysalids into paper bags, which are made use of in the majority of the parks, and hang them in some part of the boughs of the boughs of the trees, which cause gooseberries to fall off in great quantities by boring into the berry, and I found that fly to be of the same class with those which infest the apple, pear, and cherry trees. I was also able to prove decidedly, that the destruction of one hundred of eggs in a chimneystack, by opening the chimney and examining the ovarium. I also found, by carefully noticing every insect which I caught, that the greater number were females.

Having made himself completely acquainted with the enemy with which he had to contend, he continued his labors: "going over a number of wall-trees which I fixed upon for the experiment, with a branch of a willow-tree in my hand, with which I switched the leaves and branches, for it is amongst the leaves and branches of the trees the insect secretes itself; but in order that it may be done with more experience, I should refer to the observations on this subject, which were made with the assistance of two persons, one to go over the leaves and branches of the trees, in order to make the insect leave its retreat, and one with a net attached to a pole to catch the fly, or to destroy it if it should alight on the ground, as it will be apt to do, if the day is clear and sunny, for these insects cannot bear the bright rays of the sun, which is the cause of their remaining amongst the leaves during the day; but should the day be dull, the net will be highly necessary to catch the insect, as it will then likely fly to some distance before it alights. This operation must be continued until all the insects are destroyed; but it is not needful that it should be recommenced every day, as the insects are same days from the chrysalis state before they are ready to deposit their ova, which is done during night.

The method followed with standards is as follows:—The time for going over them is generally two or three days. In fact, then, one will find a wall-trees, by going over it in an hour. If an hour and a half kept with the hosing of the tree. With the standards nothing will be required but the net, as the branches can be gently shaken, which is sufficient to cause the fly to leave its nestling-place; but as it might be the means of bringing too many down at one time, if the tree was shaken all at once, care must be taken to shake the branches one by one down, so that the broken or leaf-stalks may be left as usual.

The net used is made of strong black gauze, that color being best for the purpose. It is a yard and a half in circumference, a foot deep, and attached to a whalebone rim. The handle is made of common willow, and is long enough to pass by the hand. Its use is, that it may be fastened upon the wall-tree, with which to say is, that I kept the net in my right hand; and the moment an insect was driven from its place, I swung the net in the direction opposite to that in which it flew. If I missed in the first attempt, the second generally succeeded.

The success of this plan of destroying moths has succeeded equal to my expectations; indeed it carries conviction on the face of it. It is not only simple, and can be performed at very little expense; but it is sure, and can be acted upon in the most extensive orchards. When we consider the great number of eggs one destroys by hosing a single female, in the beginning of the season, the utility of the plan I think will at once appear. Supposing, then, that any person, by going over twenty or thirty trees each day, which is done easily in a few hours, kills 200 insects; there will be no fewer than 10,000 eggs destroyed on the same trees; or, if we will measure the result by an alternation of twelve days, and in their place, the amount of eggs destroyed will be 150,000. This is actually what I have done myself: there is surely, then, very little reflection necessary, to convince any unprejudiced person, that by following the same plan, he might soon be able to bid defiance to such a formidable foe. When we also take into consideration how much the success of the crop depends upon the eggs, the result may be considered.

WATERING WITH LIME-WATER. The propriety of adopting this method must be obvious: hitherto all the plans of liming, oiling, peeling, &c. have failed." (Caled. Mem. iii. 325.)

2283. The red spider and most insects may be destroyed by the fumes of tobacco, produced by flues, the tops of which have been washed with it; or from hot plies, or by burning sulphurated paper and rags, or distilling it with a lobster. Ammoniacal gas, produced either from urine, recent stable-dung, or distillation from bones, or other substances, is also, where the air is charged with it for sometime together, an effeclue of destroying all animals. Watering, and a moist and warm atmosphere, will destroy the red-spider and keep under all insects. Heat and moisture combined, indeed, are what the gardener has chiefly to depend on, especially in every description of plant-habitation. This will appear more fully in the practical parts of this work, where the particular application of these general remarks is made to the culture and treatment of particular plants. In the meantime, the eggs and larve, are the only certain modes of preventing the ravages of the gooseberry caterpillar. As soon as the eggs which are white, and no thicker than hairs, appear on the under side of the leaf, they should be rubbed off, or the entire leaf gathered. It is true, watering the leaves well, and then dusting them with powdered quick-lime, will destroy all the eggs which will hatch from them; but the practical way is to take them when the larve are abroad, and then the caterpillars will be destroyed. Watering with lime-water is better; but even that operation is less certain, more troublesome, and not much more expeditious than hand-picking taken in time. In extreme cases, both modes may be combined.

2284. Spider-spiders may be destroyed by the fumes of tobacco from the fuming bellows, or by excessive watering.

2285. The earth-worm is most effectually kept under by watering with lime-water. Salt, vinegar, alum, or carbonated soda may be used, and be the same effect; but are injurious to vegetable, and besides, not so neutral. The lime-water, as Forsyth directs, is to be prepared by pouring water on quick-lime, and letting it stand till it settles clear, the ground infested with worms should have their casts scraped off, and then the water should be drawn from these roots in a watering-pot. The evening, and early in the morning, or on approaching rain, are the best seasons.

2286. The young gardener should carefully and assiduously study the nature, names, and classification of insects; and make himself acquainted with all the species he can pick up, either in gardens, houses, or fields. This will be the best method of increasing his professional knowledge, and will add strongly to his interest and enjoyment, at least equally so with the study of botany. For this purpose let him read the articles on insects in such Encyclopedias as come within his reach, and borrow, or otherwise procure, a reading of the works of Dr. Sherifmire, of Wood, Kirby and Spence, Donvan, Sommelle, and other authors that he will find quoted and referred to in this and other books which mention the subject.

SUBSEC. 5. Operations Relative to Diseases and other Casualties.

2287. The subject of the accidents and diseases to which plants are liable has been treated at length in the "Study of the vegetable kingdom" (Part II. Book I. Chap. IX.); and it there appeared, that very little could be done by art in curing diseases; but that much might be done to prevent them by regimen and culture, and something to the healing of wounds by amputation and exclusion of air.

F i 3
2287. The operations for the cure of accidents are chiefly cutting off injured parts, supporting, and coating over. Amputation must be performed with suitable instruments, and so as to leave a smooth section calculated to throw off the water. In cutting out large wounds which are deep, the chisel will require to be used; and in cutting off dis- eased or injured parts from small and delicate plants, a very sharp knife. Supporting the stem or trunk of bruised and wind-shaken trees, or such as are otherwise injured or rendered less secure in their general structure, is an obvious operation, and requires to be done promptly and effectually. It is also requisite in the case of cutting out such deep wounds as may endanger the stems or branches of trees or plants exposed to the free air. Coating over wounds to exclude air is a useful practice; and though it may be dispensed with in the case of small wounds on healthy plants, ought never to be neglected in the case of large wounds on any description of plants, or small ones made on such as are sickly. The usual application is now clay and loam made so thin as to be laid on with a brush, and two or three coats may be given. On large wounds paint, or putty and paint may be used; and in the case of deep hollow wounds, the part may be filled up with putty, or putty and small stones, for the sake of saving the former, and then made smooth and well painted.

2288. The operations for curing diseases are few, besides those for the cure of accidents. Washes are applied by the sponge, brush, syringe, or watering pot, for filth, mildew, and blight; and for the two latter diseases sulphur, or powdered lime is sometimes added by dregges or the hand while the plant is wet. Slighting the bark is the operation for hide-bound trees; and peeling off the outer, rough, and already separating bark by scraping-irons and bark-scalers, is resorted to in the case of old trees, as cutting out is in the case of canker. In scaling off care must be taken not to injure the inner bark; and in cutting out for canker sharp instruments must be used, and a coating applied. (See 873. to 931.)

Sect. IX. Operations of Gathering, Preserving, and Keeping.

2289. Gathering, preserving, and keeping vegetable productions, form an important part of the horticultural division of gardening. Some productions, after being reared and perfected, are to be gathered for immediate consumption; but a part require to be preserved in a state fit for culinary purposes; or for sowing or dispersing; or sending to a distant market, family or friend.

2290. Gathering vegetables or their different parts is, in part, performed with a knife, as in cutting off some fruits, as the cucumber, or heads of leaves, as the cabbage; and in part by fracture or torsion with the hand, as in pinching off strawberries between the finger and thumb, gathering peas, with one hand applied to retain the stem firm, and the other to tear asunder the peduncle, &c. In all cases of using the knife, the general principle of cutting is to be attended to, leaving always a sound section on the living plant. Gathering with the hand ought to be done as little as possible, as there are now garden-pincers for all such purposes, which do the work quicker, with far less injury to the plant, and more regard to cleanliness. Sometimes the entire plant is gathered, as in celery and onions; and at other times only the root or tuber, as in potatoes and carrots. In taking up these, care must be taken not to injure their epidermis, as on the preservation of this depends their retention of juices, beauty, and keeping.

2291. The gathering of barely fruits should take place "in the middle part of a dry day; not in the morning before the dew is evaporated, nor in the evening when it begins to be deposited. Plums readily part from the twigs when ripe: they should not be much handled, as the bloom is apt to be rubbed off. Apricots may be accounted ready when the side next the sun feels a little soft upon gentle pressure with the finger. They adhere firmly to the tree, and would over-ripen on it and become mealy. Peaches and nectarines, if moved upwards, and allowed to descend with a single jerk, will separate, if ready; and they may be received into the peach-gatherer (fig. 148.) or any tin funnel lined with velvet, so as to avoid touching with the fingers or bruising. The old rule for judging of the ripeness of figs, was to observe if a drop of water was hanging at the end of the fruit; a more certain one, is, to notice when the small end becomes of the same colour as the large end. The most transparent grapes are the most ripe. All the berries on a bunch never ripen equally; and it is therefore proper to cut away unripe or decayed berries before presenting the bunches at table. Autumn and winter pears are gathered, when dry, as they successively ripen. The early varieties of apples begin to be useful for the kitchen in the end of June; particularly the coollins and the jenneting; and in July they are fit for the dessert. From this time till October or November, many kinds ripen in succession. The safest rule is to observe when the fruit begins to fall naturally. Another easy mode of ascertaining, is to raise the fruit level with the footstalk; if ripe, it will part readily from the tree: this mode of trial is also applicable to pears. A third criterion is to cut up an apple of the average ripeness of the crop, and examine if its seeds have become brown or blackish; if they remain uncolored, the fruit is not ready for pulling. Immature fruit never keeps so well
as that which nearly approaches maturity; it is more apt to shrivel and lose flavor. Winter apples are left on the trees till there be danger of frost: they are then gathered on a dry day." (Ed. Encyc. art. Hort.) In no case should fruit be gathered with the hand when any of the different descriptions of fruit-gatherers (figs. 141. to 153.) can be used. With one or other of these, and the use of proper ladders (figs. 206. to 209.), every kind of fruit, from the gooseberry to the walnut, may be gathered without bruising, soiling, or fingerling the fruit, and without injuring the tree.

2299. The gathering of seeds should take place in very dry weather, when the seed-pods, by beginning to open, give indications of perfect ripeness. Being rubbed out with the hand, beat with a stick, or passed through a portable threshing-machine, they are then to be separated by sieves and fanners from their husks, &c. and spread out in a shaded airy loft till they are so dry as to be fit for putting up in linen or paper bags, or putting in drawers in the seed-room till wanted.

2293. Preserving heads or leaves of vegetables is effected in cellars or sheds, of any temperature, not lower, nor much above the freezing point. Thus cabbages, endive, chicory, lettuce, &c. taken out of the ground with their main roots in perfectly dry weather, at the end of the season, and laid in, or partially immersed in sand or dry earth, in a close shed, cellar, or ice-cold room, will keep through the winter, and be fit for use till spring, and often till the return of the season of their produce in the garden. The German gardeners are expert at this practice; and more especially in Russia, where the necessities being greater have called forth greater skill and attention.

2294. Flowers and leaves for decoration may be preserved by drying between leaves of paper, or in ovens; or imbedded in their natural position in fine dry sand, placed in that state in an oven. In this pot of sand they will keep for years; but they must not be taken out till wanted. When at a little distance it will be difficult to distinguish them from such as are fresh gathered. A rose is cut when the petals and leaves are perfectly dry, a little sand is put in the bottom of the flower-pot, the rose is stuck in the sand, and sand is then slowly sprinkled in till the rose be covered and the pot filled. At Paris and Milan the more popular flowers are frequently preserved in this way.

2295. Roots are preserved in different ways, according to the object in view. Tuberous roots, as those of the dahlia, preonia, tuberose, &c. intended to be planted in the succeeding spring, are preserved through the winter in dry earth, in a temperature rather under than above what is natural to them. So may the bulbous and tuberous roots of commerce, as hyacinths, tulips, onions, potatoes, &c.; but for convenience, these are kept either loose in cool dry shelves or lofts, or the finer sorts in papers, till the season of planting.

2296. Potatoes, turnips, and all similar roots which it is desired to preserve in a dormant or unvegetating state beyond the season of planting, have only to be sunk in pits to such a depth that that vegetation will not take place. A pit filled with these roots to within five feet of the surface, and the remainder compactly closed with earth, and kept quite dry, will keep one or more years in a sound state, and without vegetation. (Farmers' Mag.) For convenience of using, there should be a number of small pits, or rather of large pots of roots, so buried at a little distance from each other, as that no more may be taken up at a time than what can be consumed in a few days. The mould or compost ground will, in general, be found a convenient scene for this operation; and, for a small family, pots contrived with covers, or with their saucers, used as covers, may be deeply immersed in a large shaded ridge of earth, to be taken up, one at a time, as wanted. Grain, apples, and potatoes are kept the whole year in deep pits, in sandy soil, formed in the village-greens of some parts of Galicia and Moravia, and in banks and rocks in Spain. Oldacre informs us, in his account of his mushroom-house (Hort. Tr. vol. ii.), that he preserved broccoli in it through the winter; and Henderson, of Brechin, makes use of the ice-house for preserving "roots of all kinds till the return of the natural crop." By the month of April," he says, "the ice in our ice-house is found to have subsided four or five feet; and in this empty room I deposit the vegetables to be preserved. After stufing the vacuities with straw, and covering the surface of the ice with the same material, I place on it case-boxes, dry ware casks, baskets, &c. and fill them with turnips, carrots, beets-roots, celery, and, in particular, potatoes. By the cold of the place, vegetation is so much suspended, that all these articles may be thus kept fresh and uninjured, till they give place to another crop in its natural season.

2297. Green fruits are generally preserved by pickling or salting, and the operation is performed by some part of the domestic establishment; but in some countries it is made the province of the gardener, who, in Poland, preserves cucumbers and khol-rabbi by salting, and thenimmersing them in casks at the bottom of a deep well, where the water, preserving nearly the same temperature throughout the year, impedes their decay. It must be confessed, however, that vegetables so preserved are only fit to be eaten with animal food, as preserved cabbage (i. e. sour-crupt,) or other salted legumes.

2298. Such ripe fruit as may be preserved is generally laid up in lofts and bins, or
shelves, when in large quantities, and of baking qualities; but the better sorts of apples and pears are now preserved in sets of drawers (fig. 279.), sometimes spread out in them, at other times wrapt up in papers; or placed in pots, cylindrical earthen vessels, among sand, moss, paper, chaff, hay, sawdust, &c. or sealed up in air-tight jars or casks, and placed in the fruit-cellar. (1704.) The finest pears, as the cressannes and chaumon- telles, should have their footstalks previously tipped with sealing-wax, as practised in France and the isles of Jersey and Guernsey.

2299. Hitt’s method of keeping pears may be here mentioned. Having prepared a number of earthenware jars, and a quantity of dry moss (different species of hypnum and sphagnum), he placed a layer of moss and of pears alternately till the jar was filled; a plug was then inserted, and sealed round with melted rosin. These jars were sunk in dry sand to the depth of a foot; preferring a deep cellar for keeping them to any fruit-room.

2300. Miller, after sweating and wiping pears, in which operations he says great care must be taken not to bruise the fruit, packs them in close baskets, having some wheat-straw in the bottom and around the sides to prevent bruising, and a lining of thick soft paper to hinder the musty flavor of the straw from infecting the fruit. Only one kind of fruit is put in each basket, as the process of maturation is more or less rapid in differing kinds. A covering of paper and straw is fixed on the top, and the basket is then deposited in a dry room, secure against the access of frost, and the less air is let into the room, the better the fruit will keep.” A label should be attached to each basket, denoting the kind of fruit; for the basket is not to be opened till the fruit be wanted for use.

2301. James Stewart preserves his choice apples and pears in glazed earthenware jars, provided with tops or covers. In the bottom of the jars, and between each layer of fruit, he puts some pure pit-sand, which has been thoroughly dried on a flue. The jars are kept in a dry airy situation, as cool as possible, but secure from frost. A label on the jar indicates the kind of fruit; and when this is wanted or ought to be used, it is taken from the jars, and placed for some time on the shelves of the fruit-room. The less ripe fruit is sometimes restored to the jars, but with newly dried sand. In this way he preserves colmars and other fine French pears till April; the terling till June; and many kinds of apples till July, the skin remaining smooth and plump. Others who also employ earthenware jars, wrap each fruit in paper, and, in place of sand, use bran. (Ed. Encyc. art. Hort.)

2302. Ingram, at Torry, in Scotland, finds that for winter pears two apartments are requisite, a colder and a warmer; but the former, though cold, must be free from damp. From it the fruit is brought into the warmer room, as wanted; and by means of increased temperature, maturation is promoted, and the fruit rendered delicious and mellow. Chaumontelles, for example, are placed in close drawers, so near to a stove, that the temperature may constantly be between 60° and 70° Fahr. For most kinds of fruit, however, a temperature equal to 55° is found sufficient. The degree of heat is accurately determined by keeping small thermometers in several of the fruit-drawers, at different distances from the stove. The drawers are about six inches deep, three feet long, and two broad; they are made of hard wood, fir being apt to spoil the flavor of the fruit. They are frequently examined in order to give air, and to observe the state of the fruit, it being wiped when necessary. Ingram remarks, that, in Scotland particularly, late pears should have as much of the tree as possible, even although some frost should supervene; such as ripen freely, on the other hand, are plucked rather before they reach maturity.

2303. Winter apples are laid in heaps, and covered with mats or straw, or short or grass well dried. Here they lie for a fortnight or more, to sweat, as it is called, or to discharge some of their juice; after which the skin contracts in a certain degree. They are next wiped dry with a woolen cloth, and placed in the fruit-room. Sometimes, when intended for winter dessert fruit, they are made to undergo a farther sweating; and are again wiped and picked: they are then laid singly on the shelves, and covered with paper. Here they are occasionally turned, and such as show any symptoms of decay are immediately removed.

2304. The sweating of fruit is entirely disapproved by some, who affirm, that it thereby acquires a bad flavor, or, at any rate, that the natural flavor of the fruit is deteriorated, and that it gets dry and mealy. They consider it better to carry the fruit directly from the tree, carefully avoiding all sort of bruising, and to lay it thinly on the shelves of the fruit-room; afterwards wiping each fruit, if necessary. The room, they say, should be dry, and the only use that should be made of a stove, is to take off the damp. Such is the prevailing practice at the present time. From what we have observed in the practice of such as are successful in preserving bread corn, and other seeds, as acorns, nuts, &c. we are inclined to think that sweating, by getting rid of a quantity of moisture, must, to a certain extent, be a beneficial practice. Marshall, and most French gar-
GATHERING, which in climates sufficiently warm and favorable to bring them to maturity, is generally more firm in their texture, and more saccharine, and therefore more capable of being long preserved sound, than such as have been produced by wall-trees; and a dry and warm atmosphere also operates very favorably to the preservation of fruits, under certain circumstances, but under other circumstances, very injuriously; for the action of these elective attractions which occasion the perfect maturity of fruits is suspended by the operation of different causes, in different fruits, and even in the same fruit, in different states of maturity. When a grape is growing upon the vine, and till it has attained perfect maturity, it is obviously a living body, and its preservation dependent upon the ripening of it, and the time passed by its state of perfect maturity, and then, begun to shrivel, the powers of life are probably no longer, or at most very feeble, in action; and the fruit appears to be then preserved by the combined operation of its cellular texture, the antiseptic powers of the saccharine matter it contains, and by the exclusion of air by its external skin; for if that be destroyed, the fruit, under similar circumstances, in a dry atmosphere, is gradually converted into a raisin; and its component parts are then only held in combination by the ordinary laws of chemistry.

A nonpareille apple or a catilléa, a d‘auch, or baguette de bagi pear, exhibits all the characters of a living vegetable body long after it has been taken from the tree, and appears to possess all the powers of other similar vegetable bodies, except that of growing, or vitally uniting to itself other matter; and the experiments which I shall proceed to state, prove that the pear is operated upon by external causes nearly in the same manner as the apple, and the tree.

Most of the fine French pears, particularly the d‘auch, are much subject, when cultivated in a cold and unfavorable climate, to crack before they become full grown upon the trees, and, consequently, to decay before their proper season or state of maturity; and those which present these defects in my garden are therefore carefully taken off, and when the fruit is suspended by the operation of different causes, in different fruits, and even in the same fruit, in different states of maturity. When a grape is growing upon the vine, and till it has attained perfect maturity, it is obviously a living body, and its preservation dependent upon the ripening of it, and the time passed by its state of perfect maturity, and then, begun to shrivel, the powers of life are probably no longer, or at most very feeble, in action; and the fruit appears to be then preserved by the combined operation of its cellular texture, the antiseptic powers of the saccharine matter it contains, and by the exclusion of air by its external skin; for if that be destroyed, the fruit, under similar circumstances, in a dry atmosphere, is gradually converted into a raisin; and its component parts are then only held in combination by the ordinary laws of chemistry.

By gathering a part of my swan’s egg pears early in the season (selecting such as are most advanced towards maturity), and subjecting them, in the manner above mentioned, to artificial heat, and by retarding the maturity of the latter part of the produce of the same trees, I have often had that fruit upon the table nearly in an equal state of perfection from the end of October to the beginning of February; but the most perfect, in every respect, have been those which have been exposed in the vineyard to light and artificial heat, as soon as gathered.

The most successful method of preserving pears and apples, which I have hitherto tried, has been placing them in glazed earthen vessels, each containing about a gallon (called, provincially, steens), and surrounding each fruit with paper; but it is probable that the chaff of oats, if free from moisture or any offensive odor, will do much with advantage instead of paper, and with much less expense or trouble. These vessels, being perfect cylinders, about a foot each in height, stand very conveniently upon each other, and thus present the means of preserving a large quantity of fruit in a very small room; and if the spaces between the top of one vessel, and the base of another, be filled with a cement composed of a mixture of the curd of the curd of skirned milk, and one of lime, by which the air will be excluded, the later kinds of apples and pears will be preserved with little change in their appearance, and without any danger of decay from October till February and March. A dry and cold situation, in which there is less change of temperature, is the best for the vessels; but I have found the merits of the pears to be greatly increased by their being taken from the vessels about ten days before they were wanted for use, and being kept in a warm room; for warmth at this, as at other periods, accelerates the maturity of the pear. The same agent accelerates its decay also; and a warmer climate cannot contribute to the superior success of the French gardeners, which probably arises only from the circumstance of their fruit being the produce of standard or espalier trees.

Preserving ripe fruit by retaining it on the tree, or on detached shoots. Some fruits may be preserved by the winter by allowing them to hang on the tree in a moderate climate, somewhat above the freezing point. Vines are sometimes so preserved; and Diel mentions that frequently on the nonpareil pippin, planted in pots, and kept under glass, without any fire-heat, he has had the fruit hanging on the tree till the ripening of the succeeding crop. Arkwright (Hort. Trans. vol. iii. 97.), by late forcing, retains plump grapes on his vines till the beginning of May, and even later, till the maturity of his early crops. In this way he gathers grapes every day in the year. By covering some sorts of cherry, plum, gooseberry, and currant trees, either on walls or as bushes, with mats, the fruit of the red and white currant, and of the thicker-skinned gooseberries, may be preserved to Christmas and later. Grapes, in the open air, may be preserved in the same manner; and peaches and nectarines may, in this way, be kept a fortnight hanging on the trees after they are ripe.  

Preserving ripe fruit in air-tight vessels, in a low temperature, is perhaps the most effectual and certain mode, at least with the more hardy fruits. Apples and pears, placed in jars or pippins in which butter had been kept, have been closely sealed up, and placed in a cellar, in a temperature never below 32°, and not exceeding 42°, for a year, and found in perfect order for eating. (Braddick, in Hort. Trans. vol. iii.; Encyc. Brit. Supp. art. Food.)

Preserving fruit, by gathering it before it is ripe, and then retarding its ripening. Retarding the wasting or decay of fruit or vegetables gathered for use, is effected by burying them in boxes in the soil, immersing them in deep wells, or, as already stated, placing them in an ice-house, or an ice-cold room. Rippe peaches may thus be kept a week, and other fruits longer; pears, cauliflowers, salads, &c. preserved in a fresh state for some days, and potatoes and other tubers and bulbs for a long period, both fresh and without growing.
2310. **Seeds.** When seeds are to be preserved longer than the usual period, or when they are to be sent to a great distance, various devices have been adopted to preserve their vitality. Sugar, salt, tallow, cotton, sawdust, sand, clay, paper, &c. have been adopted with different degrees of success.

2311. **Livingston,** who, from a long residence in China, is well informed on the horticulture of the Chinese, states that, "from April to October, rain is so frequent in China, and the air is generally so moist, that it is nearly impossible to preserve seeds. If excluded from the air they are quickly covered with mildew, and when exposed, no less certainly destroyed by insects."

He proposes to dry Chinese seeds by means of sulphuric acid, in Leslie's manner, which he found dried "small seeds in two days, and the largest seeds in less than a week. Seeds thus dried," he observes, "may be afterwards preserved in a vegetating state for any necessary length of time by keeping them in an airy situation in common brown paper, and occasionally exposing them to the air in a fine day, especially after damp weather. This method will succeed with all the larger mucilaginous seeds. Very small seeds, berries, and oily seeds may probably require to be kept in sugar, or among curants or raisins." (Hort. Trans. vol. iii. 184., and the article Cold, in Supp. Encyc.Brit.) It is probable many seeds might be preserved and sent to a distance with safety, if, after being thoroughly matured and dried, they were enveloped or baked into a large ball of loam. Such a mode, at all events, being suggested by nature, deserves a trial.

2312. **Nuts from the East Indies,** compactly packed in a barrel of clay, and the head of the cask firmly put on, have made a partial development of their parts during the voyage, and still grown after their arrival. Lieutenant John Ellis says, "Fresh seeds are packed in a glass vessel with seeds, so deposited in dry sand as not to touch each other, that they may freely perspire through the sand, laying a bladder or piece of paper, over the mouth of the vessel. This glass must be placed in one of larger dimensions, the intermediate space, of about two inches all round, being quite filled with three parts nitre, one of common sea-salt, all powdered and mixed, but not dried. This mixture will produce a constant cold, so as to prevent any injury to the seeds from external heat, as has been proved by experience." (Corres. W. Linn. 110.) Ellis very correctly answers Linnaeus, that salts of no kind will generate cold air during dissolution, and that afterwards the mixture, whether dry or fluid, will soon acquire the same temperature with the surrounding air. He imagines the true use of salts to be to prevent putrefactive fermentation in the seeds. After trying a great variety of experiments on seeds and nuts sent to America, and even China, he found that of explaining acorns, then letting them become perfectly dry, and enveloping them in melted tallow, or a mixture of melted tallow and wax, was the best mode. The tallow must not be hotter than blood heat when the seeds or nuts are bedded in it; each must be kept separate; and the greatest care had that they are thoroughly dried before being enveloped. Wax alone and gum he also found successful; but, on the whole, he found tallow best. Acorns kept a year in it, grew vigorously when taken out and planted. (Corres. of Linn. p. 119. et seq.)

2313. J. Howson, when in Bengal, wrought a variety of seeds into a thick mucilage of gum Arabic, in the same way that caraway seeds are wrought into dough in making gingerbread. These he afterwards divided into small cakes, and placed them in the sun, until perfectly dry; but as a number of the seeds still appeared on their surface, he dipped the cakes in a thin solution of gum, until the whole were completely covered. On looking into a trunk, twelve years after his return to this country, he found a cake composed of gum Arabic tree seeds, which, having separated, by dissolving the cake in water, he sowed on a hot-bed, when the proportion of three out of four seeds became healthy plants. He adds, "while I was in India, none of the methods then in use were effectual for bringing out garden-seeds from England in a sound state, even although enclosed in varnished cases, and sealed bottles. It appeared to me, that the greatest heat which occupied the spaces between the ship's planks might be reduced by taking a solution of dried, putrescent Tulip seeds, in the same manner as gardeners use to mix their peat, and with this solution to produce, during the ship's passage through the warm latitudes, a musty fermentation, which inevitably destroys the living principle in seeds. It was from this view of the subject, that I was led totally to exclude air, by giving to each its own envelope." (Caled. Mem. iii. 253.)

2314. **Roots, cuttings, grafts, and perennial plants in general are preserved,** till wanted, in earth or moss, moderately moist, and shaded from the sun. The same principle is followed in packing them to be sent to a distance. The roots or root-ends of the plants or cuttings are enveloped in balls of clay or loam, wrapped round with moist moss, and air is admitted to the tops. In this way orange-trees are sent from Genoa to any part of Europe and North America in perfect preservation; and cuttings of plants sent any distance which can be accomplished in eight months, or even longer with some kinds.

Scions of the apple, pear, &c. if enveloped in clay, and wrapt up in moss or straw, and then placed in a portable ice-house so as to prevent a greater heat than 32° from penetrating to them, would, there can be little doubt, keep a year, and might thus be sent from England to Australasia or China. Knight found that the buds of fruit-trees might be preserved in a vegetating state, and sent to a considerable distance, by reducing the leaf-stalks to a short length, and enclosing the shoot in a double fold of cabbage-leaf, bound close together at each end, and then enclosing the package in a letter. "It was found advantageous to place the under surface of the cabbage-leaf inwards, by which the enclosed branch was supplied with humidity, that being the perspiring surface of the leaf, the other surface being nearly or wholly impervious to moisture." (Hort. Trans. vol. iv. p. 403.)

2315. **Packing and conveying plants in pots.** Plants in pots are packed among moss in boxes, with their tops covered with a net, and sent to any distance where the climate will not injure them, and where water is supplied. Where the climate is severe, they are covered with a glazed tegument, and thus glass cases or temporary hot-houses are employed in ships to carry tender plants from this country to the colder colonies, and to
bring plants from the warmer colonies home. Stove-plants are also transported from France, Holland, and Hamburgh, into Germany and Russia, in waggon with glass covers.

2316. In packing plants for importation, much more care is requisite than has in general been bestowed on the subject. "It is thought enough," Lindley observes (Hort. Trans. v. 192), "to bear a plant from its native soil, to plant it in fresh earth, to fasten it in a wooden case, and put it on board a vessel." Nothing can be more erroneous: preparatory for packing, the plants should have their roots well established in pots or boxes, which may, in woody kinds, require from one to three months. Boxes with proper perforations in the bottom are better than pots, because less liable to break, and of less weight. When the period for embarking them arrives, they should be placed in wooden cases, the tops of which must be changed, being sometimes, like the roof of a double green-house. These cases must be furnished with a tarpawing, fixed along their tops, and sufficiently large, when unrolled, to cover them completely, so as to protect the plants from being damaged by the salt-water dashing over them in rainy weather. These cases should not be made of very glistening paper, which would soon blot the board; and it is certain they will be handled in the roughest manner by watermen, carters, and customhouse officers, after they have arrived in port. The materials, therefore, of which they are made, ought to be of a very strong description, and the joints of the lower part either secured by iron bands, or well dovetailed together. The persons in charge of the cases on board should have directions never to exclude them from air and light in fine weather, unless to protect them from the cold, as the vessel makes the land, and after she is in port, or during high winds, or especially when the seamen are washing the decks; but in foul weather to close the lids down, and to unroll the tarpawing over the latter, so as to avoid it being disordered or injured. If, notwithstanding these precautions, saline particles should become encrusted upon the leaves and stems of the plant, it is necessary that the former should be removed as soon and as carefully as possible, with fresh water and a sponge, otherwise the salt will soon kill them. The matter of drainage should be carefully examined, and there should be holes in the case, lest the soil for the plants should become very compact. Much mischief is occasionally done to collections by monkeys and parrots on board the vessels, it is highly necessary that means should be taken to guard against their attacks.

2317. Collections are not unfrequently injured after they arrive in this country, by the pots being shaken so violently as to be deprived of a large portion of their mould. Nothing can well be more destructive of vegetable life than this, which should be prevented by the pots being made square, so as to fit accurately into the bottom of the outer case. There then could be no difficulty in keeping them steady; and if they were of the proper size, they would be secured still more completely. In addition, the surface of the mould ought to be covered deeply with coarse moss, or other similar substance (not grass), which "might be secured by packthread passed frequently across the box from its sides, or by slender wrappings, which would be less likely to become rotten than packthread." By this means, evaporation of the water particles which are necessary to the existence of the plants, proceeds much less rapidly than when the mould is exposed; and the latter has an additional security against being shaken out of the pots. When it happens that pots are not to be procured, the want of them must be supplied by the collection being planted in earth in the cases themselves, their bottom being previously strewn to the depth of an inch or two, with fragments of earth and wood. In such cases, it is particularly necessary that the mould should be securely fastened down.

2318. Parachute orchids, or, as they are commonly called, air plants, may be transported safely to any distance, by being packed loosely in moss, and put into boxes so constructed that the plants may be exposed to a free admission of air, but protected from the sea-water.

2319. Bulbs travel most safely if they are packed in paper or canvass bags, they having been previously dried, till all the moisture in their outer coats is evaporated. Dry sand is a good medium for placing them in, if quantity of water does not have to be given, and the necessity for it is supposed; but no moisturizing materials, such as those of ixias, gladiolus, oxalis, and others of a similar kind, only require to be folded in separate little parcels without any previous preparation. Terrrestrial orchids should be transplanted when in flower, and not when their roots are in a state of rest. In flowering bulbs, such as hyacinth or honey seed, unpretending, that may have been procured should be buried among the mould in which plants are potted; or any of those seeds, the juices of which become rancid soon after gathering, such as those of the guttiferes, magnolias, sterculias, &c. Camellia-seeds which are not readily transported, if sown in mould in China, will have become seeding plants before they reach this country. Acorns and walnuts may be conveyed from hot countries much better in this way than in any other. Palms, too, are better sent in this way than in bags or paper. The plants in all cases, if possible, should have numbers punched upon small pieces of thin sheet-lead, and fastened round the subjects to which they belong with fine iron or copper wire. When such lead is not to be procured, little wooden tassels should be used instead. (Hort. Trans. v. 194.)

2321. Packing and transporting roots of plants, or entire plants in a dormant state, is a very simple operation. When the distance does not exceed a week's journey, they are packed in straw, and covered with mats; if a longer period is required, the roots are enveloped in earth or moss; but very moist moss is not desirable, as it occasions mouldiness, and rots off the bark of the roots when it begins to dry. Regard in all cases must be had to the kind of plant, season of the year, distance, time, and mode of carriage.

Chap. iv.

Operations relative to the final Products desired of Gardens, and Garden-scenery.

2322. The object of gardening is certain vegetable productions, and certain beauties and effects in respect to design and taste. We now propose to notice the general principles by which the gardener ought to be guided, in directing the operations for the attainment of these ends; the mode of conducting the business of a garden in an orderly manner; and the leading points of attention, requisite to ensure the beauty and order of garden-scenery.

Sect. I. Of the Vegetable Products desired of Gardens.

2323. The vegetable productions of gardens are fruits, seeds; roots, stems, and stalks, lcv. s, flowers, barks, woods, and entire plants.
2924. Fruits. All plants require to attain the age of puberty, before they will produce fruits or seeds. In annuals, as in the melon, this happens in a few weeks or months; in trees, as the pear, it requires several years. The first object is to induce the production of blossom-buds; the next, to induce the blossoms to set or fecundate; and the third, to swell and ripen the fruit. New fruits are procured from seeds properly produced and selected; continued in trees by grafting or budding; in perennials, by slips or runners; in annuals, by seeds. The quality of fruits is improved by abundant supplies of nourishment, by increased air, light, and heat, by pruning, thinning, and other means; their bulk by moisture; and their flavor by withholding moisture and increasing light, heat, and air. Fruit is preserved by placing it in a low dry temperature, burying it in the earth, or drying it in the sun.

2925. Seeds are the essential part of fruits, or constitute the entire fruit, and are produced on the same general principle. Those produced for culinary purposes in gardening are chiefly from annuals, and used green, as the pea, bean, Indian cress, &c.; but seeds of almost all garden-vegetables are occasionally produced for the sake of propagating the species. Here attention is requisite to make choice of a proper stock, and to place it so as not to be in danger of impregnation from other allied species, which might hybridise the progeny; to thin out superfluous blossoms; to remove leafy or barren exuberances, or bulbs, tubers, or other productions which might lessen the nourishment devoted to the production of the seed. Seeds of common forest-trees are not generally subjected to so careful management as those of herbaceous vegetables or rarer trees; but, wherever the best progeny are desired, the same practises are applicable. Light, air, and a free exposure, with dry, warm weather, are essential to the proper ripening of seeds. They are preserved in dry, cool temperatures, like fruits; and, if perfectly excluded from air and moisture, will never vegetate; but the vital principle of most seeds is but of short duration.

2926. Roots, to be produced in perfection, require a deep, well pulverised, pliable, porous soil, and moderate moisture. The plants should, in all cases, be prevented from bearing seeds, should have their roots thinned where practicable, and their leaves carefully preserved, and fully exposed to the sun, air, and weather. Roots are preserved by burying in the earth; by being placed in low, dry temperatures, like fruits; or by being kept dry, or dried by art; or having their buds scooped out, when not intended for vegetation.

2927. Leaf-stalks are increased in size in the same way as roots, by a rich, deep, well pulverised soil, by preventing the plant from producing blossoms, or even flower-stalks, and by thinning out weak or crowded leaves. Leaf-stalks are blanched to lessen their astringency, as in the celery, asparagus, and chardoon, or used in a green state, as in the rhubarb and angelica. They are preserved to a certain extent in cool, dry, but well ventilated situations; some sorts, as celery, similarly to roots. The stems of some plants, as the asparagus, are used like leaf-stalks.

2928. Leaves. Abundant nourishment supplied by the usual means; abundant moisture, and room for expansion of growth; free exposure to light and air; thinning, and preventing the appearance of flower-stalks, will in general ensure large succulent leaves, which are sometimes used separately and green, as in the spinach and white beet; in tufted or compact heads, as in the cabbage and lettuce, or blanched, as in the endive. Leaves of the headed or tufted sorts may be preserved similarly to leaf-stalks; others, as those of most salads, require to be used immediately; while most herbs are dried, before being used, either on small kilns or ovens, or in the sun, at the time the plant begins to blossom.

2929. Flowers. These are produced for culinary purposes, medicine, and ornament. The principal of those grown for culinary purposes are the cauliflower and broccoli, and here the first object is to produce a large and vigorous plant, by abundant nourishment and moisture in a temperate, moist, but not over-warm climate. Free room for the roots and leaves to extend on every side must be given, and the situation should be open and exposed to the full light of the atmosphere; though, if in very hot weather the direct influence of the sun's rays be impeded by a screen at a moderate distance, there will be less risk of over-rapid growth. When the plant is fully grown, the flower appears, and, in the case of the sorts mentioned, is gathered whilst the fasciculus of blossom is in embryo. Such flowers may be preserved, on the same principle as stalks and headed leaves, for a moderate period. Other flowers, used for culinary purposes, as those of the nasturtium, caper, &c. for pickling, require less attention, the object being flavor rather than magnitude.

2930. Flowers for medical purposes should have no culture whatever; for, in proportion as they are increased in bulk they are diminished in virtue. For ornament, flowers are enlarged, increased in number, rendered double, and variegated in a thousand ways, by excess of nourishment, peculiar nourishment, and raising from selected and curiously impregnated seed: these are called florists' flowers. Other flowers are grown for ornament, with a moderate degree of culture, which enlarges their parts generally: such are border-flowers. Others are grown, as much as possible, without producing any change in their parts, as in botanical collections, whether hardy or exotic.
2331. Barks produced by British gardening are applied only to one purpose, that of tanning. Little or no culture is ever given expressly to increase or improve the bark; but abundant nourishment and all the requisites of vegetable growth will increase that part of the plant in common with others. Moss, or any other cortical parasites, should be removed. Bark is best separated from the wood, when the sap is ascending with the greatest vigor, late in spring.

2332. Woods. The production of timber, and coppice-wood or small timber, is an important and extensive branch of gardening. Timber is propagated in various ways, but the principal sorts generally from seed, either sown where it is finally to arrive at maturity, or in nursery-gardens, and transplanted into prepared or unprepared ground. The growth of all timber may be greatly increased by culture, and especially by deeply turning over, and pulverising the soil previously to planting or sowing, and stirring it, and removing weeds afterwards. The timber is also produced in the most useful, or in any desired form, as in trunks or branches, straight or crooked, or in spray or small shoots, by pruning. But as it is chiefly desired in the form of a straight stem or trunk, pruning is particularly useful in this respect, especially when joined to judicious thinning, to allow of the beneficial effects of air, and the motion produced by wind. Though pruning and pulverising the soil are undoubtedly of great use in hastening the growth of trees when young, and consolidating their timber as they grow old, yet planting trees in a more rich, warm, and moist soil than is natural to them, is to be avoided. The timber of the Scotch pine and the oak, grown in deep fertile valleys, or in alluvial depositions, is found to be less hard, tough, and durable, than when grown in colder situations and thinner soils. This doctrine applies more especially to the resinous tribe of timber-trees, which, as every one knows, thrive best in cold regions, produced by elevation in warm countries, as in the Alps of Italy, or by high latitudes, as in Russia and Sweden. Where timber is grown for fuel, the more rapidly it is made to grow, whether by culture or the choice of species (as the willow, robinia, &c.), the greater will be the produce and profit within a given period. The preservation of timber from fungi, insects, dry rot, and natural decay is best effected by immersion in water or in earth, or complete desiccation in the open air. (Supp. Encyc. Brit. art. Dry Rot.)

2333. The entire plant is produced in gardening, for ornament, in herbs, shrubs, and trees, but especially in exotics; sometimes for culinary purposes, as in the fungi and fuel; for purposes of general economy, as in hedge-plants; for shelter and shade, in hardy trees; and for picturesque effect in trees and shrubs, in parks and pleasure-grounds. In general, the object of culture for this purpose ought to be to give each individual plant sufficient nourishment and space fully to expand itself; and, as it were, show and express its nature or character: but though this will often apply in hot-houses and artificial gardens, it is in general but partially accomplished, even in picturesque scenery, in the open air, where the object is connection and grouping of different objects, rather than the display of single ones; and it is inconsistent with the formation of hedges, rows, strips, and masses.

Sect. II. Of the Superintendence and Management of Gardens.

2334. Whenever the culture and management of a garden requires more than the labor of one man, one of those employed must necessarily be appointed to arrange the labors of the rest, and, in fact, to establish a general system of management. It is only under such a system that the performance of operations can be procured in the proper season, and the objects in view successfully attained, and at a moderate expenditure.

2335. On being appointed to a situation as head gardener, the first thing to be done, in that capacity, is to survey the extent of the field of operations, and to ascertain any peculiar products or objects desired by the master, so as to determine the number of permanent hands that will be required. Then the number of implements of every kind must be fixed on and procured, and an estimate formed of the occasional hands, men or women, that may be necessary as extraordinary assistants at particular seasons. If only two or three permanent men are required, then one of them should be appointed foreman, to act as master during absence or sickness, and to have constantly the special charge of the hot-houses, or forcing and exotic departments. If, however, the situation is of such extent as to require a dozen permanent hands or upwards, then it will generally be found best to appoint a foreman to each department; as one to the artificial climates of the kitchen-garden, another to the open garden, one to the flower-garden and shrubbery, pleasure-ground, &c. (when there are plant-stoves and collections of florists' flowers, these departments should be divided), and one to the woods and plantations, unless there is a regular forester directly under the control of the master. To each of these foremen a limited number of permanent men should be assigned, and when occasion requires, assistance should be allowed them, either by common laborers or women, or by a temporary transfer of hands from any of the other departments from which they can be spared.
2336. Economical arrangements. The next thing is to fix on the hours of labor and of rest, the amount of wages, and regulations as to board, lodging, &c. The hours of labor ought to be at least one hour per day less than those for common laborers (who require no mind), in order to allow time for studying the science of the art to be practised. The amount of fines should also be fixed on at the same time: as for absence at the hours of going to labor; for defects in the performance of duty of various sorts, as putting by a tool without cleaning it, being found without a knife or apron, or not knowing the name of a plant, &c. - A set of general maxims and rules of conduct should be drawn up by the master (for which the succeeding section will afford some hints), and printed, and the amount of fine specified at the end of each rule. The fines may either be applied to some general purpose, or returned by equal distribution quarterly.

2337. The system of keeping accounts may next be determined on, and, this, in gardening, is very simple. The books necessary are, the time-book, the cash-book, and the forest or plantation book.

2338. The time-book is a large folio volume, ruled so as to read across both pages, with columns tilted, as in the specimen in the next page. In this the master inserts the name of every hand; and the foreman of each department inserts the time in days, or proportions of a day, which each person under his care has been at work, and the particular work he or she has been engaged in. At the end of each week the master sums up the time from the preceding Saturday or Monday, to the Friday or Saturday inclusive; the sum due or to be advanced to each man is put in one column, and when the man receives it he writes the word received in the column before it, and signs his name as a receipt in the succeeding column. The time-book, therefore, will show what every man has been engaged in during every hour in the year for which he has been paid, and it will also contain receipts for every sum, however trifling, which has been paid by the gardener for garden-labor. In short, it would be difficult to contrive a book more satisfactory for both master and servant than the time-book, as it prevents, as far as can well be done, the latter from deceiving either himself or his employer, and remains an authentic indisputable record of work done, and of vouchers for money paid during the whole period of the head gardener's services. In laying out grounds in a distant part of the country, where upwards of two hundred men were employed under one foreman, we had had their time, employment, and payments recorded, and receipts taken, in this way, and found it an effectual bar to every thing doubtful or disagreeable.

2339. The next book is the cash-book, (see next page,) which may be a common quarto or octavo book with horizontal lines running across both pages; Dr. and Cr. columns for cash on the left-hand page; and the right-hand page blank for a signature, or oftener, and, if requisite, the sums received from the woods and plantations can be taken out and added together, to show the amount of profit by that department. In small gardens, this is the only book that gardeners in general require to keep; but our business here is to show what belongs to first rate gardens.

2340. The forest-book, (see next page,) where that department is not an entirely separate concern, may be simply what, in Italian book-keeping, is called a waste-book. The size may be quarto, with a column for each tree, and the income and expense thereon of the book for the sale of timber, fuel, bark, or the felling of timber, grubbing, planting, &c. When the money is received for any such sale, it is entered in the cash-book; as paid for work done, it is entered in the time-book. In every extensive garden it may be necessary to open accounts, as well as for individuals who become purchasers of timber, bark, fuel, charcoal, &c.; in such cases it is hardly necessary to observe, that recourse is to be had to the common ledger of merchants.

2341. Substitutes for books. When a man acting as gardener, forester, or foreman over a number of laborers, can neither read, nor write, he may keep an account of their time, money, and a journal of work done, in various ways, and among others as follows: —

For men's time he may take seven small flower-pots for the seven days of the week and set them in order on a shelf. In each pot put as many bits of sticks as there are men employed, and a different kind of wood; and then equalize the sticks with one another as regards edges or sides. To prevent mistakes as to the individual men the different woods represent, apply the names of the woods to the men, and this from first hiring them, ("John Davies, I shall call you Lime-tree, and here is your stick," &c.) and always afterwards when speaking to them. To note their time on the sticks, let a corner notch denote one entire day; a notch half the face, one quarter; on the other side, two faces, or half a quarter stick, two quarters; on three sides, four quarters; and on four sides, a single notch and one side, five quarters, and so on. When pay night comes, take one kind of wood out of each of the pots, reckon the notches and cuts, and adding them together, call the man—"Lime-tree, your time is five days, &c.

To keep a cash-account, have three bags for gold, silver, and copper, and different-colored stones or shells, &c. in each, to represent sovereigns, shillings, &c. Then have three pots for payments, answering to the Cr. s. d. columns in a cash-account; the bags answering to the Dr. columns. Then, for every receipt have a counter, &c. So that the operation between the two shall be as follows.

To keep a ledger, for each man as represented by a sort of wood, or each object as represented by a bit of itself, &c. keep bags and pots, and effect counter-transactions, &c.

To keep a register of operations, for each man devote seven pots for a week, or two every eight for a month, &c. Then suppose you wish to move some work in the Lime-tree in the garden on Monday, put in pot of a bit of something taken from the place where he is at work, or the things he is at work with; thus, if he is at work with tan or gravel, a little of each in a paper; pruning, a twig; mowing, a little grass; watering, a bit of iris or other water-plant; or on a journey, a leaf of wayfaring-tree or a little road grist; digging, a leaf or twig from some noted tree in that compartment, &c. &c. These visible memoranda will, to a man whose memory is unencumbered by written signs, readily recall operations, and enable him after months to recount, in the order in which it was executed, the work done by himself or the men under his care. As farm-baliffs are often very illiterate, it might also be tried with them, and would at all events serve to occupy and amuse some descriptions of masters and mistresses.
### Time-Book

**1823, June 8th to 15th. Time, Expense, and Occupation of Hands employed at Aubrey Hall, under the Management of the Gardener A. D.**

#### Remarks

- The thermometer was at 90 deg. and 60 deg. the rest of the week cloudy and cold.
- The Russian ambassador, Count Bubnovsky, called on Tuesday, and Baron Schmitzoff on Friday. Tied wishes her wedding dress given her by Lady Almatis.
2342. The time, cash, and forest books, and, in common cases, the two first, will answer every purpose as to money matters in private gardens: where gardening is practised as a trade, as in nurseries, &c. of course the routine books common to trades become necessary.

2343. The additional books which a gardener may require as official records in his office are a journal of sowing and reaping, trenching-book, produce-book, and weather-book; or some of these books may be very well supplied by tables of common folio or quarto size. The sowing and reaping-book may be an octavo blank book, with a column for the date on each page. On the left hand page, the time and place of sowing or planting is recorded, and when the crop is fit to gather, that circumstance is noticed in the opposite page, and in an opposite line, thus —

<table>
<thead>
<tr>
<th>1821.</th>
<th>Sowing or Planting.</th>
</tr>
</thead>
<tbody>
<tr>
<td>April 4.</td>
<td>Planted Mazagan beans in Q. No. 1. A. Sowed spinach between the rows of beans in ditto.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>1821.</th>
<th>Gathering the Crop.</th>
</tr>
</thead>
<tbody>
<tr>
<td>July 23.</td>
<td>Gathered the first dish of beans.</td>
</tr>
<tr>
<td>May 29.</td>
<td>Gathered part of the spinach.</td>
</tr>
</tbody>
</table>

2344. Or a cropping-table may be used for this purpose (fig. 413.) in which there may be two vertical columns for each of the principal crops sown in gardens, and horizontal lines for each month. Then suppose frame peas, sown in November, begin a line on the left hand column, headed peas, opposite November, and write the variety frame in the right hand column; and when the peas are fit to gather, trace the line diagonally down to the horizontal line representing the month (May, in the figure) in which they ripen. This is a very simple mode, as it presents the sowing and reaping of the whole of the principal kitchen-garden crops at one view. A few large sheets, ruled in this manner, might be bound together; one page would serve for a year, and when a few years were recorded, the whole would present a rich assemblage of facts to suggest ideas as to cropping.

2345. The trenching-book. Another very requisite book in extensive gardens is the trenching-book, which is simply a thin octavo volume, in which a page is devoted to each compartment of the kitchen-garden or nursery, or to any ground frequently trenched; and in this column the date of the trenching and the depth is recorded. The object is to ensure fresh soil at the surface, by never trenching twice in succession to the same depth.

2346. Or a trenching-table may be easily arranged thus:

<table>

</tbody>
</table>

2347. Plan of the kitchen-garden. For the two last books or tables, as well as for a variety of other purposes, it is necessary that a plan of the kitchen-garden should be made,
and the compartments numbered, and their subdivisions lettered; and this plan, as well as another exhibiting every scene under the gardener’s care, should be framed and hung up in the office for constant reference.

2348. The produce-book may be either a quarto or octavo volume, ruled with blue lines across both pages, with a column for the date on the left-hand page, and the other blank for signatures. In this book is to be entered daily, on the left-hand page, the disposal of produce gathered or taken from the garden or garden-stores, as the fruit-room, ice-cold room, &c. On the right-hand page the name of the party in the family of the master receiving it is to be signed by the receiver as a receipt. Such books are not uncommon in first-rate gardens; and, like the game-book and cellar-book, are of very considerable use.

There is a very good model of this description, called the Naturalist’s Kalendar, by the Honorable Daines Barrington, in quarto, which may be procured and filled up. Indeed every apprentice ought to be made to keep such a kalendar, for the sake of inducing habits of observation. For further instruction, see the Naturalist’s Kalendar, of White, and Naturalist’s Pocket-book, of Graves. It has been judiciously remarked (Farm Mag. 1820.), that in all kalendars of nature, particular attention should be paid to the influence of aquatics, as these are much more regular in their times of foliage and flowering than land plants. The comparative denseness of the medium in which they live, prevents their being affected by winds or rains, and probably also by electrical and other atmospheric changes.

2350. For keeping a register of the temperature of hot-houses and the open air, a book with columns may be adopted, or a table (fig. 414.) may be fixed on, in which the ver苦难。
house or place. Twelve tables, or twelve pages of an oblong folio book ruled in this way, would keep a register of all the hot-houses, frames, and the open air of a garden for a year. A very beautiful graphic mode (fig. 415.) of recording the variations of temperature of the open air, or of any one hot-house during a year, is given by Howard, in his Climate of London, a simplification of which may be adopted by the curious gardener. Here the indicating line waves upon a circular zone, composed of radiating lines, representing time, and concentric circles representing degrees of heat. One line represents the average temperature of the year; all the degrees exceeding the average temperature are projected beyond this line towards the extremity of the zone; and all the degrees under the average are projected from the average line towards the inner circumference of the zone. A series of tables of this sort might prove useful to the gardener, by enabling him at all times, by a simple glance, to compare the present weather with that of several past years. Howard’s nomenclature of clouds, already given (1235.), deserves also the study of the gardener desirous of scientifically registering the weather. (Encyc. Brit. Sup. vol. iii. art. Cloud.)

2351. Records of the growth of plants are sometimes kept to show the comparative warmth and congeniality of seasons to vegetation. When that is to be done, a table (fig. 416.) may be composed of horizontal lines, the distance between which shall represent space in feet or inches, and vertical lines, the distance between which shall represent time by months or days. Then supposing a plant (briony) beginning to push in the middle of March, make a mark on the lowest line in the middle of the column for that month, and trace the line as the plant grows, ascending diagonally through the other months, according to the progress of the shoot in feet. If a kidneybean germinates in the beginning of April, and attains the height of ten feet by the first of September, then the indicatory line will pass through five vertical columns or months, and through ten feet, or spaces, between the horizontal lines (as in the figure). All these books, tables, and records must be kept in the office as a part of its library; by which means, when the head gardener is changed, the new-comer will the sooner become acquainted with the situation and climate, his duties, and a variety of other useful circumstances.

2352. Memorandum books. Besides the above books and tables, it is almost unnecessary to add, that various small blank books for inventories of tools, memorandums of agreements, out of door entries, lists of names, &c. will be required both by the head gardener and by his different foremen. Models of all these books may be had at Harding’s Agricultural Library, St. James’s Street, London.

2353. The reading library of the gardener’s office should at least contain the following works. One of the best Encyclopedias, and whichever one is adopted, add the Suppl. to the Encyc. Brit., the best work of its kind hitherto published. The Agricultural Survey of the County, and statistical account of the parish. If convenient, the surveys of all the counties in the empire should be procured. The best modern Systema Nature of the time; Turton’s Linneus, is very imperfect, but the only one to be had at present. The best Introduction to Botany, say that of Sir J. E. Smith, for technical or systematic botany; and that of Keith for physiology. The best catalogues of plants, say those of Sweet and Page. The best Flora Britannica for the time, say Galpine’s, or the Translation of Flora Britannica, by Sir J. E. Smith. Sowerby’s British Botany; his Mineralogy; —
and Zoology, when published. Kirby and Spence's *Introduction to Entomology*; and Samouelle's *Entomologist's Useful Companion*. The best Dictionary of Botany and Culture, say that of Miller, enlarged by Martyn. Marshall, Pontey, and Sang, on planting. Wheatley, Girardin, Price, and Repton, on laying out grounds. The *Transactions of the London and Edinburgh Horticultural Societies*. The best Gardener's *Calendar* for the time, say that of Abercrombie for England, and Abercrombie or Nicol, for Scotland and Ireland. All new works on practical gardening, if possible, as they appear. English, Latin, French, and Geographical Dictionaries, and as many other works as the master may be pleased to deposit in the gardener's office, or lend from the library of the mansion.

2354. *These books ought to be considered as for the use of journeymen and apprentices, as well as the master;* but the latter ought to be responsible for their being kept clean and perfect. Where the head gardener is of a humane and kind turn of mind, he may assemble the men and also the women, and read aloud, and expound to, or answer questions put by them; or he may cause them to read aloud to and question one another, in such a way as to blend entertainment with instruction. In short, he ought to consider it as a part of his duty to improve their minds, as well as to render them liable in his art, and by all means to ameliorate their condition and manners as much as is in his power. Neill, one of the best modern writers on gardening, and obviously a humane and benevolent man, states of the late Walter Nicol, that "he observed a praiseworthy practice, too much neglected by head gardeners,—that of instructing his young men or assistants, not only in botany, but in writing, arithmetic, geometry, and mensuration. He used to remark, that he not only used to improve his scholars, but taught himself and made his knowledge so familiar, that he could apply it in the daily business of life." The same practice, as already observed (235.), is still carried on in Germany.

**Sect. III. Of the Beauty and Order of Garden-scenery.**

2355. To unite the agreeable with the useful is an object common to all the departments of gardening. The kitchen-garden, the orchard, the nursery, and the forest, are all intended as scenes of recreation and visual enjoyment, as well as of useful culture; and enjoyment is the avowed object of the flower-garden, shrubbery, and pleasure-ground. Utility, however, will stand the test of examination longer and more frequently than any scene merely beautiful, and hence the horticultural and planting departments of gardening are, in fact, more the scenes of enjoyment of a family constantly residing at their country-seat, than the ornamental or picturesque departments. It has been a very common assertion since the modern style of gardening became prevalent, and absorbed the attention of gardeners and their employers, that beauty and neatness may be dispensed with in a kitchen-garden; but this is to assign too exclusive limits to the terms beauty and neatness; and, in truth, may be considered as originating in the vulgar error of confounding beauty with ornament, which latter quality is unquestionably not essential to scenes of utility. Every department of gardening has objects or final results peculiar to itself; and the main beauty of each of these departments will consist in the perfection with which these results are attained; a secondary beauty will consist in the display of skill in the means taken to attain them; and a third in the conformity of these means to the generally received ideas of order, propriety, and decorum, which exist in cultivated and well regulated minds. It is the business of this section to offer some general observations, with a view to the attainment of the beauties of order, propriety, and decorum. The entire work is devoted to the former beauties.

2356. *Order, it has been well observed, is "Heaven's first law." It is, indeed, the end of all law. Without it, nothing worth having is to be attained in life, even by the most fertile in resources; and with it much may be accomplished with very slender means. A mind incapable of an orderly and regular disposition of its ideas or intentions, will display a man confused and disorderly in his actions; he will begin them without a specific object in view: continue them at random, or from habit, without knowing well why, till some accident or discordant result puts an end to his present progress, unnmans him for life, or awakens reflection. But a well ordered mind reflects, arranges, and systematises ideas before attempting to realise them, weighs well the end in view, considers the fitness of the means for attaining that end, and the best mode of employing these means. To every man who has the regulation and disposal of a number of servants, this mode of orderly arrangement is essentially necessary in order to reap the full effects of their labors; and to no man is it of more importance than to master-gardeners, whose cares are so various, and the success of whose operations, always connected with, and dependent on, living beings and weather, depends so much on their being performed in the fitting moment.*

2357. *Propriety relates to what is fitting and suitable for particular circumstances; it is the natural result of an orderly mind, and may be said to include that part of order which directs the choice and adaptation of means to ends, and of ideas and objects to*
cases and situations. It belongs to order for a master to allow workmen proper periods for rest and refreshment; propriety dictates the time and duration of these periods; prudence suggests the wisdom of departing as little as possible from established practices.

2358. Decorum is the refinement of propriety. It is in order to procure stable-dung for hot-beds, and to cart it into the framing-ground; it is proper to do this at all times when it is wanted, but it is decorous to have the work performed early in the morning, that the putrescent vapors and dropping litter may not prove offensive to the master of the garden, should he, or any of his family or friends, visit that scene.

2359. Neatness, as opposed to slovenliness, is well understood; it consists in having every thing where it ought to be; and in attending to the decorum of finishing operations, and to minute things in general. These abstract hints may be considered as more particularly directed to master-operators; the following practical directions apply both to masters and their journeymen or laborers.

2360. Perform every operation in the proper season. The natural, and therefore the best indications for the operations of sowing and reaping, transplanting, &c. are given by the plants themselves, or by the progress of the season as indicated by other plants. But there are artificial kalendars or remembrancers, the use of which is to remind the master of the leading crops and operations of culture throughout the year. But, even if such books were made as perfect as their nature admits of, still they are only calculated to aid the memory, not to supply the place of a watchful and vigilant eye, and habits of attention, observation, reflection, and decision. Unless a gardener has these, either naturally, or partly natural and partly cultivated, in a considerable degree, he will be but little better than a common laborer as to general management and culture of garden-scenery.

2361. Perform every operation in the best manner. This is to be acquired in part by practice and partly also by reflection. For example, in digging over a piece of ground, it is a common practice with slovens to throw the weeds and stones on the dug ground, or on the adjoining alley or walk, with the intention of gathering them off afterwards. A better way is to have a wheelbarrow, or if that cannot be had, a large basket, in which to put the weeds and extraneous matters, as they are picked out of the ground. Some persons, in planting or weeding, whether in the open air or in hot-houses, throw down all weeds, stones, and extraneous matters on the paths or alleys, with a view to pick them up, or sweep or rake together afterwards; it is better to carry a basket or other utensil, either common or subdivided (1400.), in which to hold in one part the plants to be planted, in another the extraneous matters, &c.

2362. Complete every part of an operation as you proceed. This is an essential point in garden-operations, and though it cannot always be attended to, partly from the nature of the operation, partly from weather, &c. yet the judicious gardener will keep it in view as much as possible. Suppose a compartment, or breadth of rows of potatoes, containing one tenth of an acre, required to have the ground stirred by the Dutch hoe, the weeds raked off, and then the potatoes earthed-up with the forked hoe; the ordinary practice would be, first to hoe over the whole of the ground, then to rake it wholly over, and, lastly, to commence the operation of earthing-up. If the weather were certain of holding good two days, this, on the principle of the division of labor, would certainly be somewhat the most economical mode. But supposing the weather dry, the part left hoed and not raked will, for a time (and one hour ought to be an object in a fine garden), appear unfinished; and if rain should happen to fall in the night, the operation will be defeated in most soils. Better, therefore, to hoe, rake, and earth-up a small part at a time: so that leave off where you will, what is done will be complete.

2363. Finish one job before you begin another. This advice is trite, but it is of great importance; and there are few cases where it cannot be attended to.

2364. In leaving off working at any job, leave your work and tools in an orderly manner. Are you hoeing between rows, do not throw down your hoe blade upwards, or across the rows, and run off the nearest way to the walk the moment the breakfast or dinner hour strikes. Lay your implement down parallel to the rows, with its face or blade to the ground; then march regularly between one row to the alley, and along the alley to the path. Never drop your tools and leave off work before the hour has well done striking; and above all, never run on an occasion of this kind; it argues a gross brutalised selfishness, highly offensive to well regulated minds.

2365. In leaving off work for the day, make a temporary finish, and carry your tools to the tool-house. In general, do not leave off in the middle of a row; straighten your trenches in digging, because, independently of appearances, should a heavy rain of a week’s duration intervene, the ground will have to be re-dug, and that will be more commodiously done with a straight than with a crooked, and consequently unequal trench.

2366. In passing to and from your work, or, on any occasion, through any part of what
is considered under the charge of the gardener, keep a vigilant look out for weeds, decayed
leaves, or any other deformity, and remove them, or some of them, in passing along. 
Attend to this particularly on walks, edgings, and in passing through hot-houses, &c. In
like manner take off insects, or leaves infected by them. Much in large as well as in small gardens may be effected by this sort of timely or preventive attention, which induces suitable habits for a young gardener, and occupies very little time.

2367. In gathering a crop or any part of a crop, remove at the same time the roots, leaves,
stroms, or whatever else belonging to the plant of which you have cropped the desired part is of
no further use, or may appear slovenly, decaying, or offensive. In cutting cabbage, lettuce,
borecoles, &c. pull up the stem (with exceptions) and roots, and take them at once with
the outside leaves, to the compost-heap. Do the same with the haulm of potatoes, leaves of
turnips, carrots, celery, &c. Do not suffer the haulm of peas and beans to re-
maintain a moment after the last gathering of the crop.

2368. Let no crop of fruit, or herbaceous vegetables, or any part thereof, go to waste on
the spot. Instantly remove it when decay or any symptom of disease appears, to the
compost-yard, or to be consumed by pigs or cattle.

2369. Cut down the flower-stalks of all flowering plants, with the proper exceptions, the
moment they are fully done flowering, unless seed is an object. Cut off decayed roses,
and all decaying double flowers, with their foot-stalks, the moment they begin to decay; 
and the same of the single plants, where seed is not wanted. From May to October, the
flower-garden and shrubbery ought to be looked over by apprentices or women, every
day, as soon as the morning dews are evaporated, for this purpose, and for gathering
decayed leaves, tying up tall-growing stems before they decline or become strag-

2370. Keep every part of what is under your care perfect in its kind. Attend in spring
and autumn to walls and buildings, and get them repaired, pointed, glazed and painted,
where wanted. Attend at all times to machines, implements, and tools, keeping them
clean, sharp, and in perfect repair. With an imperfect tool, no man can make perfect work. 
See particularly that they are placed in their proper situations in the tool-house.
House every implement, utensil, or machine not in use, both in winter and summer.
Allow no blanks in edgings, rows, single specimens, drills, beds, and even where prac-
tical in broad-cast sown pieces. Keep edgings and hedges cut to the utmost nicety.
Keep the shapes of your wall-trees filled with wood according to their kind, and let
their training be in the first style of perfection. Keep all walks in perfect form, whether
raised or flat, free from weeds, dry, and well rolled. Keep all the lawns under your care,
by all the means in your power, of a close texture, and dark-green velvet appearance.
Keep water clear and free from weeds, and, if possible, let not ponds, lakes, or arti-
ficial rivers, rise to the brim in winter, nor sink very far under it in summer.

2371. Finally, attend to personal habits and to cleanliness. “Never perform any oper-
ation without gloves on your hands that you can do with gloves on; even weeding is
far more effectually and expeditiously performed by gloves, the fore-fingers and thumbs
of which terminate in wedge-like thimbles of steel, kept sharp. Most other operations
may be performed with common gloves. Thus, no gardener need have hands like bears’
paws. Always use an iron tread fastened to your shoe when you dig; and generally a
broad-brimmed, light, silk or straw hat, to serve at once as a parasol and umbrella. You
will thus save the use of your feet, lessen the wear of your shoes, and avoid the rheu-
matism in the neck. Let your dress be clean, neat, simple, and harmonious, in form
and color: in your movements maintain an erect posture, easy and free gait and motion;
let your manner be respectful and decorous to your superiors; and conduct fair and
agreeable to your equals. Elevate, meliorate, and otherwise improve, any raw, 
crude, harsh, or inharmonious features in your physiognomy, by looking often at the
faces of agreeable people, by occupying your mind with agreeable and useful ideas, and
by continually instructing yourself by reading. This also will give you features if you
have none. Remember that you are paid and maintained by and for the use and plea-
sure of your employer, who may no more wish to see a dirty, ragged, uncouth-looking,
grimining, or conceited biped in his garden, than a starved, haggard, untutored horse in
his stable.” (Travagott Schwanstepper.)

2372. He who undertakes the profession of a gardener, says the Rev. W. Marshall,
takes upon himself a work of some importance, and which requires no small degree of
knowledge, ingenuity, and exertion, to perform well. There are few businesses which
may not be learned in much less time than that of a gardener can possibly be. It often
happens, however, that a man who has been very little in a garden, and that only as a
laborer, who can do little more than dig, or put out cabbage plants, will call himself a
gardener; but he only is worthy of the name who having had much practice in the various
parts of horticulture, possesses a genius and adroitness, fitting him for making experi-
ments, and for getting through difficulties that the existing circumstances of untoward
seasons, &c. may bring him into. He should possess a spirit of enquiry into the nature
of plants and vegetation, and how far art (in his way) may be made successfully useful, or at least probably so. The mode of growth, the pruning, the soil, the heat, and the moisture that suits particular plants, are not to be understood without a native taste, and close application of the mind. Whoever will give himself the pains to trace a good gardener through the several stages of his employ, in all the seasons of the year, will find it to be one continued circle of reflection, labor, and toil. Gardening depends more upon the labor of the brain than of the body: there is no such thing as always proceeding with certainty and assuring success. Plants will die, and that sometimes suddenly, under the very best management. There are few things to be done in a garden which do not require a dexterity in operation, and a nicety in hitting the proper season for doing it. A gardener should be a sort of prophet in foreseeing what will happen under certain circumstances, and wisely cautious to provide, by the most probable means, against what may happen. A man cannot be a good gardener, except he be thoughtful, steady, and industrious; possessing a superior degree of sobriety and moral excellence, as well as genius and knowledge adapted to his business. He should be modest in his manners and opinions. It too often happens, with those who have much practical skill, that they slight what is written upon subjects of their profession; which is a fastidious temper that the man of real merit will hardly entertain.

2373. The character of a gardener is here set high; but it is the goal of responsibility at which he ought to aim who presumes to call himself a professed one. A gardener has reason, indeed, to love his employment, as he meets with health and tranquillity in the exercise of it; but considering what he is, and what he does, in his proper capacity, he may justly claim a superior degree of estimation and reward. A true gentleman is of a liberal spirit, and I would plead for his gardener as a proper person to be generous towards, if his manners be good. (Introduct. to Gard. p. 447.)

---

PART III.

GARDENING AS PRACTISED IN BRITAIN.

2374. The art of gardening in the earlier ages of society would be practised without those local subdivisions, or technical distinctions, which its progressive improvement has since rendered necessary; and being then carried on in one enclosure, called a Garden, the term Gardening was then sufficiently explicit for every purpose. But at present the local subdivisions and technical distinctions of this art are various; we have the kitchen, fruit, flower, forcing, and exotic gardens, the pleasure-ground, shrubbery, park, and timber-plantation, all within the province of Gardening; and the terms culinary gardening, fruit-gardening, flower-gardening, planting, &c. as technical distinctions for them. The vague manner in which so many terms have been used by gardeners and authors, has led to some confusion of ideas on the subject, which it is much to be wished could be avoided in future. Taking the word gardening as a generic term, we have arranged its ramifications or divisions, in what we conceive to be permanent or specific distinctions. The principle of classification which we have adopted, is that of the use or object in view; and applying it, we think all the varieties of gardening may be included under the four following species: —

2375. Horticulture, the object of which is to cultivate products used in domestic economy. It includes culinary and fruit gardening, or orcharding; and forcing or exotic gardening, as far as respects useful products.

2376. Floriculture, or ornamental gardening, the object of which is to cultivate plants ornamental in domestic economy. It includes flower, botanical, and shrubbery gardening; and forcing and exotic gardening, as far as respects plants of ornament.

2377. Arboriculture, or planting, the object of which is to cultivate trees and shrubs, useful in general economy. It is practised in forests, woods, groves, copses, stripes, and rows.

2378. Landscape-gardening, the object of which is to produce landscapes; or, so to arrange and harmonise the external scenes of a country-residence, as to render them ornamental, both as domestic scenery, and as a part of the general scenery of the country. This branch is by some called picturesque, rural, ornamental, or territorial improvement; rural ornament, ornamental gardening, pictorial improvement, new ground work, ornamental planting, &c. It includes the ancient, formal, geometric, or French gardening, and the modern, natural, picturesque, or English gardening.
There are other terms applied to gardens and gardening; as nursery, market, physic, &c. gardens, and nursery-gardening, market-gardening, &c.; but these concern gardening as a trade, rather than as an art, and their discussion is referred to the succeeding part of this work, in which gardening is considered statistically.

BOOK I.

HORTICULTURE.

2380. In treating of horticulture, some, as Nicol and Abercrombie, have neglected its local unity, and adopting its technical subdivisions, treated of the culinary fruit and forcing departments, as if they were separate gardens. But as these departments are all generally carried on within the same ring-fence, and as it is impossible to form and arrange a kitchen-garden, without at the same time forming and arranging the walls and borders destined to receive the most valuable part of the fruit garden, and equally so to lay out the area enclosed, without determining the situation and extent of the forcing-department, we deem it preferable to treat of Horticulture as actually carried on, and in the following order: viz. — The formation of the kitchen-garden. The distribution of the fruit-trees. The forming and planting of a subsidiary orchard. The general culture of the kitchen-garden. The general culture of the orchard. The construction of buildings used in the forcing-department. The general culture of the forcing-department. Catalogue of plants and trees used in horticulture. A monthly table of horticultural productions.

CHAP. I.

The Formation of a Kitchen-garden.

2381. The arrangement and laying out of a kitchen-garden, embraces a variety of considerations, some relative to local circumstances, as situation, exposure, soil, &c.; others depending on the skill of the artist, as form, laying out the area, water, &c.: both require the utmost deliberation; for next to a badly designed, ill placed house, a misplaced, ill arranged, and unproductive kitchen-garden is the greatest evil of a country-residence.

SECT. I. Situation.

2382. The situation of the kitchen-garden, considered artificially or relatively to the other parts of a residence, should be as near the mansion and the stable-offices, as is consistent with beauty, convenience, and other arrangements. Nicol observes, "In a great place, the kitchen-garden should be so situated as to be convenient, and, at the same time, be concealed from the house. It is often connected with the shrubbery or pleasure-garden, and also placed near to the house. There can be no impropriety in this, provided it be kept in good order, and that the walls be screened by shrubbery from the immediate view of the public rooms; indeed it has been found, that there is both comfort and economy in having the various gardens of a place connected, and placed at no great distance from the house. In stepping from the shrubbery to the flower-garden, thence to the orchard, and lastly to the culinary garden, there is a gradation both natural and pleasant. With such an arrangement, in cases where the aspect of the ground is answerable, and the surface, perhaps, is considerably varied, few faults will be found."

2383. Sometimes we find the kitchen-garden placed immediately in front of the house, which Nicol "considers the most awkward situation of any, especially if placed near, and so that it cannot be properly screened by some sort of plantation. Generally speaking, it should be placed in the rear or flank of the house, by which means the lawn may not be broken and rendered unshapely where it is required to be most complete. The necessary traffic with this garden, if placed in front, is always offensive. Descending to the consideration of more humble gardens, circumstances are often so arbitrary with respect to their situations, as that they cannot be placed either so as to please, or give satisfaction by their products. There are cases where the kitchen-garden is necessarily thrust into a corner, and perhaps is shaded by buildings, or by tall trees, from the sun and air; where they are placed on steep hangs in a northern aspect, the sub-soil is a till or a cankering gravel, and the site cold and bleak. Such situations as these are to be avoided, and should be considered among the worst possible. Next are open, unsheltered plains. But even there, if the soil be tolerably good, and the sub-soil be not particularly bad, shelter may be reared, so as that in a few years the garden may produce a return for the expense laid out in its improvements." (Kalender, p. 8.)

2384. To place the fruit and kitchen gardens at perhaps half a mile’s distance or more from
the house was formerly the prevailing taste. In many cases, Neill observes, "this has been found inconvenient, and it can seldom happen that the garden-walls may not be effectually concealed by means of shrubs and low growing trees, so as not to be seen, at least from the windows of the public rooms, and the garden yet be situated much nearer to the house. It is scarcely necessary," he adds, "to observe that an access for carts and wheelbarrows, without touching the principal approach, is indispensable." (Ed. Encyc. art. Hort.)

2385. With respect to the natural situation of a garden, Nicoll and Forsyth agree in preferring a gentle declivity towards the south, a little inclining to the east, to receive the benefit of the morning sun. "If it be situated in a bottom, the wind will have the less effect upon it; but then dams and fogs will be very prejudicial to the fruit and other crops; and if situated too high, although it will in a great measure be free from dams and fogs, it will be exposed to the fury of the winds, to the great hurt of the trees, by breaking their branches, and blowing down their blossoms and fruit." (Tr. on Fruit Trees, p. 286.)

2386. The situation should not be so elevated as to be exposed to boisterous and cutting winds; nor should a very low situation be chosen, if circumstances afford any choice. It should be situated conveniently for access from the house. (Abercrombie's Practical Gardener, p. 1.)

2387. Avoid low situations and bottoms of valleys, say Switzer, Darwin, Bradley, and Lawrence, "because there is often a sourness in the earth that cannot be eradicated, and in this uncertain climate of ours, such heavy fogs and mists that hang so long on the fruit and leaves in low situations, that not only vegetation is retarded, but also the fruit." (Pract. Fruit Gard. 2d edit. p. 19.) "The greater warmth of low situations," Dr. Darwin observes, "and their being generally better sheltered from the cold north-east winds, and the boisterous south-west winds, are agreeable circumstances; as the north-east winds in this climate are the freezing winds; and the south-west winds being more violent, are liable much to injure standard fruit-trees in summer by dashing their branches against each other, and thence bruising or beating off the fruit; but in low situations the fogs in vernal evenings, by moistening the young shoots of trees, and their early flowers, render them much more liable to the injuries of the frosty nights, which succeed them, which they escape in higher situations." (Phytologia, sect. xv. 3. 6.) Professor Bradley "gives a decisive fact in regard to this subject. A friend of his had two gardens, one not many feet below the other, but so different, that the low garden often appeared flooded with the evening mists, when none appeared in the upper one; and in a letter to Bradley he complains that his lower garden is much injured by the vernal frost, and not his upper one. A similar fact is mentioned by Lawrence, who observes, that he has often seen the leaves and tender shoots of tall ash-trees in blasting mists to be frozen, and as it were singed, in all the lower parts and middle of the tree; while the upper part, which was above the mist, has been uninjured." (Darwin's Phytootha, sect. xv. 3. 6.)

2388. Main entrance to the garden. Whatever be the situation of a kitchen-garden, whether in reference to the mansion or the variations of the surface, it is an important object to have the main entrance on the south side, and next to that, on the east or west. The object of this is to produce a favorable first impression on the spectator, by his viewing the highest and best wall (that on the north side) in front; and which is of still greater consequence, all the hot-houses, pits, and frames in that direction. Nothing can be more unsightly than the view of the high north wall of a garden, with its back sheds and chimney-pots from behind; or even getting the first coup d'ceil of the hot-houses from a point nearly in a parallel line with their front. The effect of many excellent gardens is lost or marred for want of attention to this point, or from peculiarity of situation. Even the new garden of the London Horticultural Society, when finished according to their engraved plan, will be obnoxious to it: the Chelsea garden is liable to the objection, and those of Oxford and Liverpool particularly so.

2389. Bird's-eye view of the garden. When the grounds of a residence are much varied, the general view of the kitchen-garden will unavoidably be looked down on or up to from some of the walks or drives, or from open glades in the lawn or park. Some arrangement will therefore be requisite to place the garden, or so to dispose of plantations that only favorable views can be obtained of its area. To get a bird's-eye view of it from the north, or from a point in a line with the north wall, will have as bad an effect as the view of its north elevation, in which all its "baser parts" are rendered conspicuous.

Sect. II. Exposure and Aspect.

2390. Exposure is the next consideration, and in cold and variable climates is of so much consequence for the maturation of fruits, that the site of the garden must be guided by it, more than by locality to the mansion.

2391. The exposure should be towards the south, according to Nicol, and the aspect at some point between south-east and south-west, the ground sloping to these points in
an easy manner. If quite flat, it seldom can be laid sufficiently dry; and if very steep, it is worked under many disadvantages. It may have a fall, however, of a foot in twenty, without being very inconvenient, but a fall of a foot in thirty is most desirable, by which the ground is sufficiently elevated, yet not too much so. (Kalender, p. 6.)

2392. An exposure declining towards the south, is that approved of by Switzer, "but not more than six inches in ten feet. Two or three inches he considers better." (Pract. Fruit Gard. 2d edit. p. 17.)

2393. An open aspect to the east, Abercrombie observes, "is itself a point of capital importance in laying out a garden, or orchard, on account of the early sun. When the sun can reach the garden at its rising, and continue a regular influence, increasing as the day advances, it has a gradual and most beneficial effect in dissolving the hoar frost, which the past night may have scattered over young buds, leaves, and blossoms or setting fruit. On the contrary, when the sun is excluded from the garden till about ten in the morning, and then suddenly darts upon it, with all the force derived from considerable elevation, the exposure is bad, particularly for fruit-bearing plants, in the spring months; the powerful rays of heat at once melt the icy particles, and immediately acting on the moisture thus created, scald the tender blossom, which drops as if nipped by a malignant blight; hence it happens, that many a healthy tree, with a promising show of blossoms, fails to produce fruit; the blossoms and thawed frost sometimes falling together in the course of a morning. The covering of the hoar frost, or congealed dew, is otherwise of itself a remarkable preservative of the vegetable creation from frosty winds." (Pract. Gard. p. 1.)

2394. An exposure in which is a free admittance for the sun and air, is required by Forsyth, who rejects a place surrounded by woods as very improper, because a foul stagnant air is very unfavorable to vegetation; and it is also observed that blights are much more frequent in such situations than in those that are more open and exposed. Such an exposure will generally be to the south (fig. 417. d, e), but much depends on the surrounding scenery. For this reason the northern boundary of a garden, where the hot-beds are generally placed, will admit most sun and air, in proportion to the open space, when of a rounded (as in fig. 417. d, e), rather than an angular form; especially if the plantation (fig. 418. a), which surrounds the garden gradually decline in height as it approaches the hot-bed ground (b), on the north, and the surrounding walk (c), on the other sides.

2395. If there be any slope in the area of a garden, Marshall considers "it should be southward, a point to the east or west not much signifying; but not to the north, if it can be avoided, because crops come in late, and plants do not stand the winter so well in such a situation. A garden with a northern aspect has, however, its advantages, being cooler for some summer productions, as strawberries, spring-sown cauliflowers, &c.; therefore, to have a little ground under cultivation, so situated, is desirable, especially for late succession-crops." (Introduct. to Gard. 5th edit. p. 8.)

Sect. III. Extent.

2396. The extent of the kitchen-garden must be regulated by that of the place, of the family, and of their style of living. In general, it may be observed, that few country-seats have less than an acre, or more than twelve acres in regular cultivation as kitchen-garden, exclusive of the orchard and flower-garden. From one and a half to five acres
may be considered as the common quantities enclosed by walls, and the latter size, under proper management, with abundance of manure, is capable of supplying a respectable establishment. Where a farm is cultivated by the proprietor, it is found a desirable practice to have part of the more common kitchen-crops, as cabbages, turnips, peas, potatoes, carrots, &c., grown in the fields; the flavor of vegetables so grown being greatly superior to that of those raised in a garden by force of manure. Where a farm is not kept in hand, by annually changing the surface of the garden by trenching (2343.), this effect of enriched grounds is considerably lessened.

2397. To assist in determining the extent of a garden, Marshall observes, that an acre with wall-trees, hot-beds, pots, &c. will furnish employment for one man, who, at some busy times, will need assistance. The size of the garden should, however, be proportioned to the house, and to the number of inhabitants it does, or may contain. This is naturally dictated; but yet it is better to have too much ground allotted than too little, and there is nothing monstrous in a large garden annexed to a small house. Some families use few, others many vegetables; and it makes a great difference whether the owner is curious to have a long season of the same production, or is content to have a supply only at the more common times. But to give some rules for the quantity of ground to be laid out, a family of four persons (exclusive of servants) should have a rood of good-working, open ground, and so in proportion. But, if possible, let the garden be rather extensive, according to the family; for then a useful sprinkling of fruit-trees can be planted in it, which may be expected to do well under the common culture of the ground about them; a good portion of it also may be allotted for that agreeable fruit the strawberry in all its varieties; and the very disagreeable circumstance of being at any time short of vegetables will be avoided. It should be considered also that artichokes, asparagus, and a long succession of peas and beans, require a good deal of ground. Hot-beds will also take up much room, if any thing considerable be done in the way of raising cucumbers, melons, &c. (Introd. to Gard. p. 25.)

2398. For a small family, two acres of ground will do; but if for a great family, it should be six or eight acres. (Justice's Brit. Gard. Direc. p. 1.)

2399. The size of a garden may be from one acre to six or eight within the wall, according to the demand for vegetables in the family. (Forsyth.)

SECT. IV. Shelter and Shade.

2400. To combine adequate shelter, with a free exposure to the rising and setting sun, is essentially necessary, and may be reckoned one of the most difficult points in the formation of a garden.

2401. The kitchen-garden should be sheltered by plantations; but should by no means be shaded, or be crowded by them. If walled round, it should be open and free on all sides, or at least to the south-east and west, that the walls may be clothed with fruit-trees on both sides. (Nicol, Kal. p. 6.)

2402. The garden should be sheltered from the east, north, and west winds, by hills, rising grounds, high buildings, or plantations of trees, at such a distance on the east and west sides, as not to prevent the sun from shining upon it. (M'dPhail, Gard. Rem. 2d edit. p. 12.)

2403. A garden ought to be sheltered as much as can be from the north and east winds. These points of the compass, Marshall observes, should be guarded against by high and good fences, by a wall of at least ten feet high; lower walls do not answer so well for fruit-trees, though one of eight may do. A garden should be so situated as to be as much warmer as possible than the general temper of the air is without, or ought to be made warmer by the ring and subdivision fences. This advantage is essential to the expectation we have from a garden locally considered. As to trees planted without the wall, to break the wind, it is not to be expected to reap much good this way, except from something more than a single row; i.e. a plantation. Yet the fall of leaves by autumnal winds is troublesome; and a high wall is therefore advisable. Spruce firs have been used in close shorn hedges; which, as evergreens, are proper enough to plant for a screen in a single row, though not very near to the wall; but the best evergreens for this purpose are the evergreen oak and the cork-tree. The witch-elm, planted close, grows quick, and has a pretty summer appearance behind a wall; but of little use then, as a screen, except to the west; when still it may shade too much (if planted near) as it mounts high. In a dry hungry soil, the beech also is very proper, and both bear cutting. The great maple, commonly called the sycamore, is handsome, of quick growth, and being fit to stand the rudest blasts, will protect a garden well in a very exposed situation; the wind to be chiefly guarded against as to strength, in most places, being the westerly. (Introd. to Gard. p. 27.)

2404. To shelter an elevated garden on a steep declivity (fig. 419.), it may require to be surrounded on all sides by high woods (n), and even to have groups of evergreens, as pines and hollies (e), and hedges of trellis or lattice-work (p, p), within the garden. The
hot-houses (d) and hot-beds (f) may be placed, and more delicate culinary crops (h) cultivated, in an artificial basin or hollow, which will have the advantage of being sheltered both naturally and artificially, and on a steep exposed to the south, will have a powerful influence in accumulating heat in winter from the sun's rays. The south borders of such gardens (l, m), and the walls heated by furnaces (g), will frequently be found to produce earlier crops than gardens placed on level surfaces and in low sheltered situations.

2405. Shelter may in part be derived from the natural shape and situation of the ground. Gentle declivities, Neil observes, at the bases of the south or south-west sides of hills, or the sloping banks of winding rivers, with a similar exposure, are therefore very desirable. If plantations exist in the neighbourhood of the house, or of the site intended for the house, the planner of a garden naturally looks to them for his principal shelter; taking care, however, to keep at a reasonable distance from them, so as to guard against the evil of being shaded. If the plantations be young, and contain beech, elm, oak, and other tall-growing trees, allowance is of course made for the future progress of the trees in height.

It is a rule that there should be no tall trees on the south side of a garden, to a very considerable distance; for, during winter and early spring, they fling their lengthened shadows into the garden, at a time when every sunbeam is valuable. On the east also, they must be sufficiently removed to admit the early morning rays. The advantage of this is conspicuous in the spring months, when hoar-frost often rests on the tender buds and flowers: if this be gradually dissolved, no harm ensues; but if the blossom be all at once exposed to the powerful rays of the advancing sun, when he overtops the trees, the sudden transition from cold to heat often proves destructive. On the west, and particularly on the north, trees may approach nearer, perhaps within less than a hundred feet, and be more crowded, as from these directions the most violent and the coldest winds assail us. If forest-trees do not previously exist on the territory, screen-plantations must be reared as fast as possible. The sycamore (Acer pseudo-platanus) is of the most rapid growth, making about six feet in a season; next to it may be ranked the larch, which gains about four feet; and then follow the spruce and balm of Gilead firs, which grow between three and four feet in the year. (Edin. Encyc. art. Hort.)

2406. A garden should be well sheltered from the north and east, to prevent the blighting winds from affecting the trees; and also from the westerly winds, which are very hurt-
ful to the gardens in the spring or summer months. If a garden be not naturally sheltered with gently rising hills, which are the best shelter of any, plantations of forest-trees, made at proper distances, so as not to shade it, will be found the best substitute.

(Forsyth, Tr. on Fruit Trees, p. 286.)

2407. A garden should be well “guarded with wood,” on the north-east, south-west, and north-west; the south and south-east being the only aspects that should be open. This, Switzer says, is of “great import.” There is great danger as to the easterly exposition, inasmuch as all blighting winds come from that quarter; so also the south-west is subject to the violent concussions of those winds that come off from the Atlantic or western ocean. But, it may be observed, the sun acting in an oblique manner, and the winds fluctuating horizontally, the garden may be planted all round with wood, between ten and fifteen yards’ distance, provided you keep your trees on the south side to about fifteen feet high, for security from winds, without any danger of depriving it of the benefit of the sun. (Pract. Fruit Gard. 2d edit. p. 18.)

2408. Shade as well as shelter are attended to by Abercrombie, who observes, “that competent fences are serviceable in sheltering tender seedlings, and in forming warm borders for early crops and winter standing plants; while in another direction some part of the line of fence will afford a shady border in summer, which is required by the peculiar constitutions of many small annual plants. Where a kitchen-garden encloses two, three, or four acres, it will admit cross walls at proper distances, by which the advantages just mentioned may be multiplied.” (Prac. Gard. 2d edit. p. 3.)

Sect. V. Soil.

2409. The soil of a garden is obviously of the greatest consequence in its culture. It is, however, a subordinate consideration to situation and exposure, for the soil may be changed or improved by art; but no human efforts can remove the site, or change the exposure of a plot of ground. This subject was much more attended to about a century ago, in the days of London and Wise, Switzer and Hitt, than it seems to be at present. Gardeners, in general, depending too much on manures, and other adventitious aids, for securing large, though sometimes ill-flavored, culinary crops. Jethro Tull has some coarse, but to a certain extent just remarks on this subject. As an auxiliary argument in support of his delusive doctrine of rejecting manure in culture, he affects to “wonder that gentlemen who are so delicate in other matters should make no scruple to cat vegetables and fruits grown among the vilest filth and ordure.” (Treatise on the Horse-hoeing Husbandry, 3d edit. p. 30.)

2410. The best soil for a garden, McPhail observes, “is a sandy loam, not less than two feet deep, and good earth not of a binding nature in summer, nor retentive of rain in winter; but of such a texture, that it can be worked without difficulty, in any season of the year. It should be remembered, that there are few sorts of fruit-trees, or esculent vegetables, which require less depth of earth to grow in than two feet to bring them to perfection; and if the earth of the kitchen-garden be three or more feet deep, so much the better; for when the plants are in a state of maturity, if the roots, even of peas, spinach, kidneybeans, lettuce, &c. be minutely traced, they will be found to penetrate into the earth, in search of food, to the depth of two feet, provided the soil be of a nature that allows them. If it can be done, a garden should be made on land whose bottom is not of a springy wet nature. If this rule can be observed, draining will be unnecessary; for when land is well prepared for the growth of fruit-trees and esculent vegetables, by trenching, manuring, and digging, it is by these means brought into such a porous temperament, that the rains pass through it without being detained longer than necessary. If the land of a garden be of too strong a nature, it should be well mixed with sand, or scrapings of roads, where stones have been ground to pieces by carriages.”

(Gard. Rem. p. 12.)

2411. A hazel-colored loam, or a blackish vegetable earth, according to Abercrombie, “may be regarded as good; or if it be a fat loam mixed with silvery sand, or a moderately light mellow loam. A bed of very light sand or gravel is to be rejected, unless the alternative would give you a soil solutions of oil, a limited proportion of those earths contributes to form a rich and generous soil. Chalk may abound in a higher proportion than clay, and sand in a higher proportion than either clay or chalk, without causing barrenness. The soils best adapted for moderating the excesses, and compensating the deficiencies of heat and moisture in different seasons, are compositions of sand, pulverised chalk, and finely divided clay, with a proportion of animal or vegetable matter. If the soil be not naturally good to the depth of thirty inches, and thence to three feet, proper earths and composts should be incorporated with it, to make it so, where the tenure does not render the expense unadvisable. It should be done where it is intended to found a
complete kitchen-garden; not, indeed, because many esculent plants require more than eighteen inches' depth of good earth, in order to flourish in perfection; nor that even fruit-trees generally will not thrive for a considerable course of time in a suitable soil, full two feet in depth, although three feet on their account is better; but, in order that the gardener may have it in his power to give rest to alternate portions of the soil, without keeping the surface out of crop, by trenching in successive years to different depths, so as to bring any given layer, measuring a spit in thickness, by turns to the bottom, the middle, and the surface, in proportion as the natural soil is unfavorable, it should receive improvement, till it be gradually brought to the desired state. Where something intractable must be taken away, as in the case of a very stony bed, let the ground be trenched, and the larger stones screened or raked out: ameliorate the residue by such earths, manures, and composts as its defects may require. To give heart to excessively light, sandy, and unstable ground, incorporate with it substantial loam and well rotted dung. To correct a cold stubborn clay, add drift sand, shell marl, seaweed, warm light earth, and well-rotted dung. To qualify soot for application in a garden, mix a thirty-sixth part with a heap of compost. If the soil has been rendered cold and wet by the passage and lodgment of water, it is requisite to have the ground effectually drained." (Pract. Gard. p. 2.)

2412. The soil that suits general cultivation best is a loam, rather the red than the black, Marshall observes; "but there are good soils of various colors, and this must be as it happens; the worst soil is a cold heavy clay, and the next a light sand; a moderate clay, however, is better than a very light soil, though not so pleasant to work. If the soil is not good, i.e. too poor, too strong, or too light, it is to be carefully improved without delay. Let it first, at least, be thoroughly broken, and cleared of all rubbish, to a regular level depth at bottom as well as top, so as to give about eighteen inches of working mould, if the good soil will admit of it; none that is bad should be thrown up for use, but rather moved away. This rule of bottom-levelling is particularly necessary when there is clay below, as it will secretly hold up wet, which should not stand in any part of the garden. When a piece of ground is cleared of roots, weeds, stones, &c. it would be of advantage to have the whole thrown into two-feet wide trenches, and lie thus as long as conveniently may be. The ground cannot be too well prepared; for when this business is not performed to the bottom at first, it is often neglected, and may not be conveniently done afterwards; so it happens, that barely a spade's depth (or less) is too often thought sufficient to go on with. There is this great advantage of a deep staple, that in the cultivation of it the bottom may be brought to the top every other year, by double-trenching; and being thus renewed, less dung will do, and sweeter vegetables be grown. Tap-rooted things, as carrots and parsneps, require a good depth of soil." (Introd. to Gard. p. 28.)

2413. The soil of a new garden should be two or three feet deep, according to Forsyth; "but if deeper the better, of a mellow pliable nature, and of a moderate dry quality; and if the ground should have an uneven surface, by no means attempt to level it, for by that unevenness, and any little difference there may be in the quality, you will have a greater variety of soil adapted to different crops. The best soil for a garden is a rich mellow loam; and the worst, a stiff heavy clay. A light sand is also a very unfit soil for a garden. Sea-coal ashes, or the cleanings of streets and ditches, will be found very proper to mix with a strong soil; and if the ground should be cold, a large quantity of coal-ashes, sea-sand, or rotten vegetables should be laid upon it, in order to meliorate and loosen the soil, and render it easy to work. Lime-rubbish, or light sandy earth from fields and commons, will also be found of great service to stiff clayey ground. If the soil be light and warm, rotten neat's dung is the best dressing that you can give it. If horse-dung be ever used, it must be completely rotted, otherwise it will burn up the crop the first hot weather." (Tr. on Fr. Trees, p. 290.)

2414. Different soils are required in the same garden. This is Nicol's opinion, who has had more experience in the formation of gardens than any of the authors from whom we are quoting; his remarks "on soils, and how to improve them," merit every attention, and will be duly valued by those who have seen any of the excellent kitchen-gardens he has formed in Fifeshire, Perthshire, and other northern counties. It is a happy circumstance, he says, "that in many instances we meet with different soils in the same acre." In the same garden they should never be wanting; and where nature (or natural causes) has been deficient, recourse must be had to art; inasmuch as the variety of fruits and vegetables to be cultivated require different soils to produce them in perfection. It would be absurd, however, to imagine, that for every particular vegetable there is to be a particular soil prepared.

2415. The varieties of soil in any garden may, with propriety, be confined to the following: — Strong clayey loam, light sandy loam (which are the two grand objects), a composition of one fourth strong with three fourths light loam, half strong and half light, and one fourth light and three fourths strong. These, by a proper treatment, and with the proper application of manures, may be rendered productive of any of the known and commonly cultivated vegetables in the highest degree of perfection.
In order to improve a soil, we must be guided much by its nature, so as, if possible, to render it serviceable for general purposes. And hence our duty is to endeavour to hit on that happy medium which suits the site and climate, for improvements, in the same manner as an artist will, in the picture of a landscape. In this way a soil should be sufficiently tenacious to adhere to the roots of plants, though not so much as to be binding, which would certainly retard their progress and extension in quest of food. Hence a loam of a middle texture, rather inclining to sand, may be considered as the most suitable soil for the purpose here in view. It has the double advantage, viz. the greater part of the valuable kinds of kitchen-vegetables delight in such soil, and it is worked at less expense than a stiff one; neither in severe droughts is it apt to crack or be parched, nor in hard frost is it so apt to throw out tender plants or seeds.

The surfacing of the soil, to the extent of a layer of planter and pebbles, and if a soil be too light, and if it be poor without, plants deposited in it will push their roots far, and in vain, in quest of that stability and nutriment which is necessary and essential to their support. So that if the butt of our aim be perfection in the production of wholesome and well matured vegetables, we must put aside carelessness in the formation of the soil, and consider the proper soil for the crops, as they even to be had in the greatest plenty; for dungs, by too free an application, have an effect on the quality of esculents not altogether salutary. Wherefore, that our efforts may be attended with success, let us abstain from a moderate and prudent expense in the first outset, on composting or so improving the soil to be applied in a judicious manner, as the best judge of the local soil and climate, and by being carefully laid up in ridges in the winter months, and, indeed, at all times when not in crop, in such a manner as to give the greatest extent of surface for the weather to act upon; where the soil is a poor sand, or gravel, by the addition of clay, or strong clayey loam, scoublings of ditches which run through a clayey sub-soil, pond-mud in a like situation, or scrapings of roads which lie in a clayey district, &c.

Soils that abound with metallic substances, and which generally make them appear of an inferior color, are termed fox bent or till. These substances are often found to be intimately mixed, or rather consolated with sand particles, in considerable quantities, which a mellow soil is most unfavorable to vegetation of any, and are quite ineligible for the purpose here in view, without being much improved. For this purpose, lime will be found the most serviceable of all things, if judiciously, and if the soil be frequently turned over, so that the lime may be intimately vegetation mixed together, and that the atmosphere may have full effect upon them; for without this, the lime will not operate so effectually, nor will the tily particles of the soil be divided or mollified so well. It may seem unnecessary to observe, that, according to the quantity of iron matter contained in the soil, will determine the time of reducing the lime, for it will be found useful, and one of the masses being calcined, and then reduced to a powder, the magnes will separate the iron particles from the soil, showing the proportion of iron and of earth. Thus we may fertilise the soil, taking for the extremes in ordinary cases, and supposing the lime of a middling quality, 1/2 and 1/4 Winchester bushels an acre; applying the lime in a quick or powdered state, and properly working the soil, being careful in the first place, to drain it of superabundant moisture.

Ridding up of soil, as above hinted at, has the happiest effect, especially for stiff soils, and should never be omitted when the ground is not under crop. In dead sandy loams also, and in cankering gravels, it is of incalculable advantage, and greatly meliorates them. For it is a fact proved by experience, that exposing soil to the sun’s rays in part, by throwing it into a heap, whereby it is also partly shaded, and trenching it once a month, or in two months, will sooner restore it to fertility than any other process, excepting the annual manuring. And thus, if any abundant good soil be in hand, it may be expelled, or be exhaled by the action of the atmosphere, more particularly if the soil undergo a summer and also a winter fallow. In the latter case, however, care should be taken to have the surface encrusted by frost, as often as possible, by turning it, and giving it a new surface each succeeding spring.

The soil intended for a garden may be known by its productions. “In selecting ground for a garden,” Nell observes, “the plants growing naturally on the surface should be noted, from these a pretty correct opinion may be formed of the qualities of the soil. The sub-soil should also be examined. If this be radically bad, such as an iron till mixed with gravel, no draining, trenching, or manuring will ever prove an effectual remedy; if, on the contrary, the sub-soil be tolerably good, the surface may be greatly meliorated by these means. In every garden two varieties of soil are wanted, a strong and a light one, or, in other words, a clayey loam and a sandy loam; different plants requiring these respective kinds. For the general soil, a loam of middling quality, but partaking rather of the sandy than the clayey, is accounted the best.” (Ed. Encyc. art. Hort.)

In general practice. It appears to be generally agreed on by practical men, that there ought to be between two and a half and four feet of good soil over the whole surface of the kitchen-garden. This depth will rarely be found to exist naturally; or, if it does in some places, it will be deficient in others. The proper heights for the borders and compartments being fixed on, and the whole thoroughly drained, the next thing is to trench the soil to the proper depth from the level or levels of the intended surface, whether these run under or over the present surface, removing all unfavorable sub-soil, either to such hollows within the ring-fence of the garden as require to be filled up to a greater depth than that fixed on for the good soil; or, what is preferable, placing it without the garden. This done, the next thing is to introduce as much good soil as will raise the surface to the thickness required. The strongness or lightness of this additional soil must depend on the nature of that already there, and on the object in view. In complete gardens, it may be desirable to have three qualities of soil, viz. a strong loam or light loam, and a loam of medium quality; the latter occupying the borders and about half of the compartments. The soils introduced therefore must be such as, with what is naturally there, will effect these objects. If, for example, the local soil is everywhere light or sandy, then one part, say, that destined for strong loam, should receive as much of clayey loam as will bring it to the temperament desired; that for medium loam a lesser portion, with as much light earth as will bring it to the required depth: and if the
natural soil is deemed too light, to that also must be added a portion of what is more cohesive, &c. It may be observed, however, that the general object in selecting, forming, or improving the soil for a kitchen-garden, is to obtain, as Nicol expresses it, “a loam of a middle texture rather inclining to sand,” such soil being easy to work, little affected by either droughts, rains, or frosts; and the greater part of the valuable kinds of kitchen-vegetables delighting in it. All the authors we have quoted above may be said to agree in desiring such a soil for the whole of the kitchen-garden. In peculiar situations, as where villas are built on rocky steeps, and other romantic situations, it may become a matter of great difficulty and expense to bring soil from a distance; and it may also be found equally difficult to find a bed for it, by the removal of rock, &c. In such cases, all that can be done is to select the most favorable spots (fig. 420. a, a); cultivate them to the utmost, connect them by walks and shrubbery; and place the economical buildings attached to the garden (b), and hot-houses, &c. (c), in the most commodious situations, and where they will not interfere with general effects. There are many very productive gardens of this description in the north of Scotland, and in the territory of Genoa.

**Sect. VI. Water.**

2423. *A copious supply of water* is essential to a good kitchen-garden, and, from whatever source it is furnished, should be distributed either in reservoirs or open cisterns, or in pipes, properly protected, over the garden, and in hot-houses. If the supply is from a pond or river, a system of lead or cast-iron pipes may be adopted, and the delivery effected by cocks at proper distances; but if from wells or springs, the delivery should be into open stone or cast-iron cisterns; or, in default of these, into tubs or butts sunk in the earth. In Tuscany, where the inhabitants excel in the manufacture of pottery, immense jars of earthenware are frequently adopted; in the Royal Garden at Paris, sunk barrels; and cisterns of masonry, lined with cement, are general in the best gardens on the continent. In these gardens, a system of watering is adopted, which, though rendered more necessary there by the climate, than it can possibly be in this country, yet in various respects deserves imitation.

2424. *Many kitchen-crops are lost, or produced of very inferior quality, for want of watering.* Lettuces and cabbage are of a tender and stringy nature; turnips and radishes do not swell, onions decay, cauli-flowers die off, and, in general, in dry seasons, all the cruciferous become stunted, or covered with insects, even in rich deep soils. Copious waterings in the evenings, during the dry seasons, would produce that fulness and succulence which we find in the vegetables produced in the Low Countries, and in the Marsh Gardens at Paris; and in this country at the beginning and latter end of the season. The vegetables brought to the London market from the Neat’s Houses, and other adjoining gardens, where the important article of watering is much more attended to than in private country-gardens, may be adduced as affording proofs of the advantage of the practice.

2425. The watering the foliage of fruit and other trees to destroy or prevent the increase of insects, and of strawberries and fruit-shrubs to swell the fruit, is also of importance; and though the climate of Scotland is less obnoxious to great droughts, than that of the southern counties, yet we find that excellent horticultural architect, John Hay, adopting a system of watering in various gardens lately formed by him in the neighbourhood of Edinburgh.

2426. *The contrivance for watering or washing the foliage of the wall-trees in Dalmeny garden,* laid out by this artist, deserves particular notice. Water is supplied to the garden from a reservoir, situated on an eminence, a considerable height above the garden-walls. Around the whole garden, four inches below the surface of the ground, a groove, between two and three inches deep, has been formed in the walls, to receive a three-quarter inch pipe for conducting the water. About fifty feet distant from each other are apertures through the wall, two feet and a half high, and ten inches wide, in which a cock is placed, so that on turning the handle to either side of the wall, the water issues from that side. The nozzles of the cocks have screws on each side, to which is attached at pleasure a leather pipe, with a brass cock and director; roses, pierced with holes of different sizes, being fitted to the latter. By this contrivance, all the trees, both inside and outside the wall, can be most effectually watered and washed in a very short space of time, and with very little trouble. One man may go over the whole in two hours. At the same time the borders, and even a considerable part of the compartments, can be watered with the greatest ease when required. The convenience and utility of this contrivance must at once be perceived by every practical horticulturist. The ingenious plan of introducing water is adopted in a garden which J. Hay planned and executed for Lord V. Duncan, at Lundie-House, near Dundee; and after the experience of several years, it has been greatly approved. The water at Lundie is conveyed to the garden from a considerable height, and is thrown from the point of the director with great force, and to a good distance. (Edin. Encyc. art. Hort.)

2427. *Water in a garden is absolutely necessary,* according to Justice; well-water is far from being proper, but that which is impregnated by the sun’s rays is highly condu-
cive to vegetation. He recommends forming a large pond or basin in the centre of the garden, which shall at the same time contain fish. (Brit. Gard. Direct. p. 2.)

2428. Gardens should be near a river or brook, that they may be well supplied with water. From these, Forsyth observes, "if the garden does not lie too high, the water may be conducted to it by drains; or, which is much better, by pipes, taking care to lay them low enough to receive the water in the driest season, which is the time when it will be most wanted. If there be no running water near the garden, and if the latter lies on a declivity near a public road, I would advise to make a hollow drain, or a cut, from the most convenient part of the road, to receive the water that washes the road in rainy weather, and convey it to a large cistern, or tank, in the upper part of the garden; this, if the road be mended with limestone or chalk, will prove an excellent manure. The water from the cistern, or from the river, may be conducted to the different compartments by means of pipes, which, having cocks at proper places, the water may be turned upon the different compartments of the garden at pleasure. Or the water may be conveyed in proper channels, and turned on the compartments in the same manner as in watering meadows. These pipes, channels, &c. will be a considerable expense at first; but they will soon repay it, by saving a great deal of time, which would otherwise be spent in pumping and carrying water. The most convenient time for turning the water on is, in general, during the night; and in dry weather it would then be of the most essential service. If the situation be such that you are obliged to pump the water from deep wells, there should be a large reservoir, in which it should be exposed to the sun and air for some days before it is used; it may then be turned on as above. If the ground be wet and swampy, it will be proper to make a basin of the most convenient place to receive the water that comes from the drains, and to collect the rain that falls on the walks."

(Tr. on Fr. Trees.)

2429. Water is the life and soul of a garden. Switzer observes, "it is one of the most essential conveniences of a country-seat, and especially useful to kitchen-crops; for, indeed, what can be made of any ground without it? Anima mea sicut terra sine aqua, is a good metaphor to express it, as it really is the soul and life of all vegetation; and whoever does not make that one of his principal considerations, deserves blame or pity." Describing his design for the garden of Spy Park as to water, the same author observes, "The square basins are not only designed for little stews for fish, but at each corner there are clay and elm pipes, with plugs to them that go under the alley, and communicate themselves with the adjacent divisions or compartments, which will, in an instant, float the same, because the little basins are designed to lie six inches higher than those divisions or compartments; and then the whole is so contrived by other larger elm pipes, that the said little basins are filled by the canal and other conveniences."

2430. A source of water is considered essential to a garden by most writers. London and Wise, Evelyn, Hitt, and Lawrence are warm in recommending it. M'Phail observes, that a garden to bring the produce of the soil to the greatest perfection, "should be well supplied with water, to water the plants in dry seasons." (Gard. Rem. 2d edit. p. 13.) If water can be introduced, observes Marshall, "... and kept clean with verdant banks around it, it would be very useful where a garden is large; but let it be as near the centre as possible, being the most convenient situation. It should be fed from a spring, and (if it could) be made to drip in the reservoir, because its trickling noise is agreeable music in a garden to most ears." (Intro. to Gard. p. 42.) "If there be no natural stream that can be conducted through a garden," observes Nicol, "water should be conveyed from the nearest river, lake, or pond; soft water being most desirable for the use of the garden." (Kalendrar, p. 7.)

Sect. VII. Form.

2431. In regard to form, almost all the authors above quoted agree in recommending a square (fig. 421. a) or oblong, as the most convenient for a garden; but Abercrombie proposes a long octagon, in common language, an oblong with the angles cut off (b); by which, he says, a greater portion of the wall in the slips behind will be on an equality with the garden as to aspect.

2432. A geometrical square is recommended by Hitt, "set out in such a manner, that each wall may have as much benefit of the sun as possible," that is, with reference to the compass, set out as a rhomboid (c).

2433. A square or oblong form, M'Phail considers as the most convenient. A square with a semicircular projection on the north side (fig. 417. d), or a parallelogram with a
northern projection in the form of a semicircle (fig. 417. e), were favorite forms with the late W. Nicol. These opinions, it is to be considered, refer more properly to the space enclosed by walls than to the whole garden, which ought to be considered as comprehending the entire space included in the ring-fence; which fence, choice or accidental circumstances may produce in any shape from the circle (fig. 424.) to the most irregular figure. (figs. 420. 422.)

2434. The oval, polygonal, and trapezium forms have been adopted for the walls of a garden, in order to procure a more equal distribution of sun and shade; but the inconvieniences attending the culture and management of the compartments of such gardens are considerable; nor does it appear an equal distribution of sun is so suitable, as that of having some walls as advantageously exposed as possible for the more delicate fruits; and others less so for hardier sorts, for retarding fruits, and for growing plants to which shade is congenial in the borders. No figure whatever can add to the quantity of sun's rays received by the whole form, but merely vary their distribution.

2435. Even irregular figures are admissable, such figures (fig. 422.) being surrounded by wood (i), and interspersed with fruit-trees, will form very agreeable shapes in walking through them; and while the compartments are thrown into right-lined figures to facilitate culture, the angles can be occupied with fruit-trees or shrubs, permanent crops, as strawberries, asparagus, &c. with the hot-houses (e), or other buildings (b), or with ponds (f), and other adjuncts. Some of the walks may be wavy (a), as a direction indicated by the outline of wood, and one main walk (d, d) may be formed, broad and straight, to display the whole.

Sect. VIII. Walls.

2436. Walls are built round a garden chiefly for the production of fruits. A kitchen-garden, Nicol observes, considered merely as such, may be as completely fenced and sheltered by hedges as by walls, as indeed they were in former times, and examples of that mode of fencing are still to be met with. But in order to obtain the finer fruits, it becomes necessary to build walls, or to erect pales and railings.

2437. Placing, proportioning, and constructing the walls of a kitchen-garden, is a matter in which the artist may display a degree of taste, as well as fitness and propriety. "If these," Nicol continues, "be properly set down, so as to answer the cast of the ground (fig. 423.), and be raised to proper heights, according to its extent, the rest is easy, and follows as a matter of course. In this particular branch of gardening, utility and simplicity ought to go hand in hand, otherwise true taste will be wanting. It is not in curves, circles, and ogees, we shall find satisfaction. The walls, if the ground admit of it, should all run in direct lines, corresponding to the slopes on which they are placed (a, b, c, d); they may be built level, or they may be inclined, so as to suit the general cast of the ground; but the nearer to a level the better they will please. The mind is dissatisfied and distracted in beholding any building apparently unstable. We can look upon a mast placed oblique, or on a tree growing aslant, with firmness and satisfaction, because we know the one is supported by ropes, and the other by roots; but on a wall running much off the level, we look with a degree of distrust or of fear. If the north wall can be placed quite level, and also the south wall on a lower level, and so as that the east and west walls shall fall, from north to south, a foot in thirty or in twenty-five; and if the ground be lengthened from east to west, in the proportion of three to two, the extent being two or three acres, on such a spot may be formed a garden that will not fail to please.
Next, on a spot of the above, or of similar dimensions, sloping to the south, and not level from east to west, but sloping a few feet, perhaps one in fifty, to the east, in this case the opposite walls should run directly parallel to each other, both with respect to latitude and to inclination, otherwise the eye will be displeased by the distorted appearance of the coping when at the full height. Next, all as here described, and the ground sloping to the south and to the west. And next, a dead level spot, in which case particularly the walls should be of different heights. But ground falling to the north, or much distorted, should be avoided, as being very unfit for erecting walls or other buildings upon, on which a complete modern garden cannot be formed without considerable difficulty, and a great additional expense." (Kalend. p. 142.)

2438. Walls with a south aspect, as Switzer observes, "have been all along reckoned the best for fruits, though later observation and experience have not confirmed it; for when the days are something long, and the heat of the sun in its greatest strength, it is late before the sun shines upon them, and it leaves such a position as early in the afternoon. Besides, when it is mid-day, the sun is so much elevated above the horizon, that it shines but faintly and very slopingly upon them, which makes the heat to be much the less, inasmuch as a smaller quantity of rays fall upon such a wall, it being visible, that both before and after noon the sun shines hotter than when it is in its highest meridian. From whence, 'tis natural to infer, that a little inclination, either to the east or west, are the best aspects; but which of the two will maintain its precedence may be now enquired into. And in this inquiry, I shall venture to affirm, that the east, or rather south-east, are to be preferred to the west or south-west, though they are as much exposed to the sun as east walls are. Though it should be argued that the sun shines stronger in the afternoon than the morning, because it continues to act on air already warmed with the influence of the morning sun, yet, inasmuch as the rays of the sun are more healthy and cheerful than after, and dispel the cold dews and vapors as before, it is more than equivalent to the extraordinary heat of the afternoon sun, as experience shows, which is generally languid and unhealthy. From whence I infer as before, that the south-east maintains its post against either the south or south-west. 'Tis from reasons of this kind I would venture to establish it as my humble opinion, (and I think I have the suffrage of most eminent planters and gardeners to second me,) that a south wall, inclining about twenty degrees to the east, is preferable to any of the others, inasmuch as the sun shines as early on it as on a full east wall, and never departs from it till about two o'clock in the afternoon; besides, it is something removed from those destructive winds that come from the west and north." (Pr. Fr. Gard. p. 312.)

2439. Equality of aspect. Hitt proposes to have no south wall, but by the position of the four sides of his garden (fig. 421. c) endeavors to obtain a comparatively equal distribution of solar heat. The plan he recommends contains two acres, the ground descending from the south-west side. "In respect to the aspect of the walls," he says, "the sun's rays continue no longer upon the north-west wall than three in the afternoon, which, I think, is the most proper aspect for grapes, peaches, nectarines, and all other kinds of fruit that require the most regular heat to bring them to perfection, and soonest to maturity, for though the sun leaves this wall so soon in the afternoon, yet in the morning this aspect will be of advantage to the trees and fruits; for, as apricots, peaches, and nectarines blossom early in the spring, at which time our climate is frequently attended with frosty nights, destructive of both blossoms and fruit, the sun's rays darting in lines at right angles upon the wall at nine o'clock, dissolve the congealed moisture much sooner than if they darted upon it at right angles at noon, which they must consequently do if the wall stands due south. 'Tis true, a south wall will receive more sun by three hours, that is, from about three in the afternoon till near six, (in the vernal equinox,) but that is no great advantage, for before that time of the day the air will be sufficiently warmed. Besides, if the wall is built full south, it will not be so proper for fruit-trees as a south-east aspect; for in the middle of the day the sun will cause the trees to exhale their juices faster than their roots can absorb them, which will render the fruit smaller and the pulp harder, and worse flavored, than those which receive the heat more regular. The south-east wall receives the sun about nine o'clock, which is a proper situation for some of the best kinds of winter pears, and which they well deserve, for they afford fine juices and rich flavors, when other fruits of the same quality are wanting. Some kinds of grapes, peaches, and nectarines will ripen well against it; and this has one equal advantage with the south-west wall, viz. of the sun's rays striking obliquely upon it at noon. The north-west aspects of these walls receive but little sun, for he shines not upon them till three in the afternoon, but they will serve for fruits which ripen in summer, as cherries, plums, and some kinds of pears." (Pr. on Fruit Trees, p. 33.)

2440. A full south aspect is recommended by Marshall, for a wall designed for the best fruits; or, it may be somewhat inclining to the east, by which it will catch the sun's rays at its rise, the cold night dews will be earlier and more gently dissipated, and the scorching rays of the afternoon summer's sun are sooner off. By thus having the walls of a
WALLS.

2441. The best aspect for a fruit-wall in Scotland, Nicol observes, "is about one point to the eastward of south, such walls enjoying the benefit of the morning sun, and being turned a little from the violent west and south-west winds. South-east is, for the same reasons, accounted by many a better aspect than south-west." Dr. Walker, on the other hand, with reference to the same country, states, that the six hottest hours of the day are from eleven to five o'clock, and that it is not a wall of a south-east, but of a south-west aspect, which enjoys this heat. (Essays on Nat. Hist. p. 258.)

2442. The height of walls for training fruit-trees generally approved is from ten to twelve feet; but it is more commonly determined by the size and form of the garden, and the inclination of its surface. The following judicious observations of Nicol are the best which have appeared on this subject. The irregular surfaces on which gardens are often obliged to be formed in Scotland, require the greatest attention and nicety from the designer, and hence the fulness of his remarks.

2443. With respect to the height of fruit-walls, considered merely as such, the matter might easily be determined. I would say, twelve feet, that height being very convenient for the operations of pruning, watering, gathering the fruit, &c. and admitting of a sufficient expansion of the branches of most trees. But the height of garden-walls should be regulated by the extent, or by the apparent extent, of the ground enclosed by them. I say by the apparent extent, as well as by the real extent, because much depends on the form and cast of the ground, in which the eye shall be pleased. If it be a square, it will seem less than it really is; and if a lengthened parallelogram, larger; and according to its flatness or its elevation, the eye will be deceived.

2444. A small plot surrounded by high walls has a bad effect and a gloomy appearance. The walls being of different heights give relief. In a garden of an acre, being a parallelogram of the best proportion, and gently elevated, the north wall may be raised to the height of fourteen feet; the east and west walls to twelve; and the south wall to ten feet above the ground level. If the ground slope considerably, the height in the respective heights of the walls may be less; they may be only a foot; and the relief will be the same, or nearly the same, to the eye, in ranging along their surfaces. In a garden of greater extent, the walls may be raised to a greater height; but by no means in proportion, if it extend to several acres. The extreme height of the north wall of any garden should not exceed eighteen feet; and containing suppose four acres, the east and west walls should be fifteen, and the south wall only twelve feet high, in order that it may give the necessary relief to the eye. In a garden four hundred feet long and three hundred feet broad, which forms a handsome parallelogram, and contains something above two English acres, if the ground lie on an easy slope, a very eligible height for the north wall is sixteen feet; for the east and west walls fourteen; and for the south wall twelve. But if the ground be quite level, or nearly so, the north wall being the same height, the east and west walls should only be thirteen, and a half feet, and the south wall eleven feet in height; or the east and west walls may only be thirteen, and the south wall ten feet high, if it be a dead level. (Kal. p. 165.)

2445. Fruit-walls five or six feet high, Hitt observes, will do very well for peaches, cherries, vines, and figs, but he would not advise the planting of plums, apricots, or pears, on such walls, they requiring more room, and to stand longer before they bear.

2446. Fruit-walls ten feet high are preferred by Forsyth, but he says they may extend to fourteen feet.

2447. Many low walls, or stout ranges of paling, Abercrombie observes, "will produce a greater total effect in accelerating fruit, than the same expenditure in high walls."

2448. The situation of the garden-doors in the walls demands attention. We have already shown the importance of entering the garden from the south, south-east, or south-west sides; and this circumstance must not be lost sight of for main entrances. Doors in the north wall, or north ring-fence, should be considered as exclusively for the operators of the garden. Doors, in short, should be so contrived, as never to invite visitors to the north slip, or so as to get behind the hot-houses. The width of doors depends on the extent of the garden, and whether the melon-ground and compost-ground are within the walls, or in the external area. In general the doors in the ring-fence, and the walk round the outside of the garden, should be as similar as to admit a one-horse cart for bringing in manure and soils.

2449. The sloping or bevelled walls, recommended by the author of Fruit Walls improved by inclining them to the Horizon, are disapproved of by Switzer, because, "though the author's very curious calculation is, perhaps, no whit inconsistent with truth, yet experience has taught (and that in a sloping wall at Belvoir Castle, I think, of the author's own directing), that though the sun may act with more vigor in its solstitial capacity on a sloping than on a perpendicular wall, yet it is as deficient in its performances in the morning; and by the author's own arguments, as well as the observations of almost every body that has made any observation at all, that dews are expelled at least an hour in the morning sooner from a perpendicular wall than a sloping one; so that what is gained at one time is lost at another." (Pract. Fr. Gard. p. 314, 315.)

2450. Other modifications of kitchen-garden walls. Hitt observes, "I have seen some walls stuck with tiles projecting, called horizontal shelters, some built with large pillars, and others with curves; all these are attended with evils of one kind or other; for the horizontal shelters are great receptacles of noxious insects, particularly of the small green
and variegated caterpillars. These insects devour the leaves and eat deeply into the fruit when grown to a good size; so that it perishes and drops off the trees. The shelters are likewise very prejudicial to both fruit and branches, by depriving them of the descending dew, from which they imbibe great nourishment. Large pillars or piers have almost the same ill effects; besides, they shade the rays of the sun from the trees part of the day, more or less, in proportion to their size. Though walls built with curves have, in calm seasons, the benefit of more heat than others; yet, in windy weather, the winds from some point or other rebounding from side to side, break and destroy the tender branches and blossoms of trees, whereby they are much more injured than the heat reflected from one wall to the other can be of advantage to them. I have found by experience, that walls built straight and upon arches, as mentioned before, are preferable to all others, having a coping which projects about two inches to shoot off the rain, in order to preserve the wall.” (Tr. on Fruit Trees, p. 40.)

2451. With respect to the construction of walls for kitchen-gardens, the common upright, straight wall is now generally preferred to the sloping, angular, or curved walls, tried in several places about a century ago, and criticised by Justice, Miller, Switzer, and other authors of that day. There may occur cases, however, in which these uncommon forms, and others which we have noticed (1556 to 1575.), may be adopted with propriety. A very good application of the angular wall, when formed of boards, may be made in the case of a circular garden. (fig. 424.) At each angle (a, b) a light cast-iron post with grooves is to be inserted in the ground; and in these grooves, the ends of the boards, say in six or eight feet lengths, are to be inserted, and left without any fastening. If they shrink during summer, being loose, they will only drop a little, but never show any crevice; and, in order to let the trees be fully exposed to the weather in winter, or to paint, repair, or renew the boards, all or any part of the latter may easily be taken out, leaving the cast-iron props in the grounds, and the trees as entirely detached as if they were standards or border bushes (d). In this way, a large surface of cheap and neat walling might be obtained in very little space, and on the whole an agreeable effect produced. A walk, shrubbery and hedge (c) may surround the whole.

2452. Fruit-walls, according to Hitt, should be founded on piers, “placing them at such distances as to admit one tree of the sort proper for the aspect between, and forming them of dimensions suitable to the size of the walls, and the nature of the foundations. The advantages he states to be a saving of material and intended pasturage for the root. If, however, the wall is to be planted with fruit-trees on both sides, the latter advantage is imaginary; and, indeed, the construction might often prove injurious by admitting the hardy roots of trees, fit for a northern exposure, to intermix with the more delicate ones of such as are planted on a south aspect. Justice, having disapproved of curved and angular walls, says, “and as to the other methods of arching walls at their bottoms, that is still worse; for when the roots go out at the back sides of the walls at their freedom, they draw all the rancid juices from the earths at the backs of the walls: in consequence of which, the fruit infallibly falls off, after it has acquired its magnitude, &c.” (Brit. Gard. Direct. p. 5.) A late writer, J. Robertson (Hort. Trans. iv. p. 95.), recommends such walls for peach-trees, but obviously on the supposition that no use is made either of the north side of the wall, or north border.

2453. The foundation of a garden-wall, according to McPhail, should be dug out no deeper than the thickness of good earth on the surface, in order that as little wall may be lost as possible.

2454. Fruit-walls may be strengthened by piers, according to Forsyth, placed from forty to sixty feet apart, and projecting half a brick beyond the wall. Such piers are now made round, or rounded off, as the technical term is, which is more convenient for training trees.

2455. Projecting stone buttresses are, in some places, set at intervals in the walls, Nell informs us, in order to strengthen them, and break the force of the winds when sweeping along. From the external angles of the walls of Dalmeny Park gardens,
where they meet at right angles, a wall (fig. 425. a), is extended diagonally about seventeen feet. This extension is found very useful in breaking the force of the wind when ranging along the walls. At the same time it does away, in a considerable degree, the formal box-shape of the garden when viewed from the higher grounds in the neighborhood. (Ed. Encyc. art. Hort.)

2456. With respect to the coping of garden-walls, Nicol observes, "much has been said, and opinions are at variance. Some insist that the coping should not project beyond the face of the wall; and others, that it should project several inches, in order to throw the drip off the foliage. Others, again, give it a slope to the north, or to the west side, in order to throw all the water to the first aspect, or to that not covered with trees. It may be right to throw the whole of the water to the side not covered with fruit-trees; but it is wrong to throw it all to the worst aspect, if that aspect be planted, by being disadvantageous to the trees trained on it, if there be any disadvantage in the rains falling upon them; which, indeed, is questionable, except, perhaps, just when the fruit is ripening off. The quantity of rain that falls on an ordinary wall, is but trifling; and if even a light breeze of wind prevail at the time, it is generally dashed against the foliage in dripping, or is scattered and dissipated. In short, it is quite as well for the trees that there be no projection at all, if the coping be fixed. A temporary coping of boards, projecting perhaps a foot or eighteen inches, may be of service to the trees in spring, while in bloom, in repelling the perpendicular frosts, that are often injurious to them at that time, and to the tender fruit. But such frosts are more hurtful than baneful frosty winds, which fall not perpendicularly, and which are better warded off by screens." (Kol. p. 146.)

2457. Fixed copings are disapproved of by Forsyth, especially when they project so far as they are generally made to do. "I would rather advise to have a moveable wooden coping, fixed on with iron hooks, fastened to pieces of wood, built into the top of the wall; these copings would also be found very convenient to fasten the nettings, &c. to in spring, for sheltering the fruit-trees. If, however, any should prefer fixed copings, they should not project above an inch on each side of the wall; this small projection will be sufficient to preserve the wall, and will not prevent the dew and rain from falling on the upper part of the trees, which is of great service to them."

2458. Copings which project nearly a foot are approved of by the Comte Leliure, and the Rev. T. G. Cullum. In the best peach-gardens at Montreuil they project four or five inches; and at Thomery, where the finest grapes are raised, the copings project ten or eleven inches over walls which do not exceed eight feet in height. (Pom. Francaise, p. 78.) T. G. Cullum has built, in Suffolk, a nine-inch wall with rounded pier, and copings of slate supported by oak brackets, projecting a foot from the wall. The result answered his expectations. (Hort. Trans. iv. 269.)

2459. Estimate of opinions as to copings. On the whole, it appears both from the experience of a number of gardeners, and the most correct theories of dew (Wells on Den, 1819, see 1243.) and cold (Leslie, in Supp. Encyc. art. Cold), that projecting copings are of use in spring to protect the blossoms from descending cold and dew; but as the copings must be injurious in summer by excluding light, rain, and air, and harboring vermin, we should prefer the temporary coping of boards recommended by Miller, Forsyth, and Nicol.

2460. With respect to the materials for kitchen-garden walls, brick is almost universally preferred; Forsyth says, "Where brick cannot be got, it is better to dispense with walls altogether, or to adopt wooden ones." "Brick," Nicol states, "is best for the superstructure, and stone for the foundation and basement. Bricks give more warmth, and answer better for training trees to than stone. South, east, and west aspects should therefore be faced with brick, if the wall be not entirely built of it. If the wall be built entirely of stone, or be backed with stone, or be faced with bricks, and if trees are to be trained against such backing, the stones should be run in regular courses of from four to seven or eight inches thick, and each fifteen or twenty inches in length, by which there may be a frequency in joints, and that the trees may be properly trained against the wall."

2461. Dark-colored whinstone (greenstone or basalt) is the next best material to brick, when properly squared and hammer-dressed, as it absorbs heat; and next to that, a kind of bluish-grey stone (sandstone flag), or, in parts of the country consisting of primitive rocks, clay-slate that rises in natural flags, the thickness, or nearly the thickness, of bricks, and which require but little dressing, or trouble in building. The nearer the stone approaches to black, the more valuable it is for the purpose; the preference being given to the darkest whinstone, merely because it absorbs and retains heat more than light-colored stones, and by reason of its close texture or grain, repels moisture better, or retards less of it than other stones. But good durable freestone (sand-stone), being properly squared, hammer-dressed, and run in courses as above, makes a very good wall for training the more common kind of fruits to; such as apples, cherries, pears, and plums, and may answer very well for east, west, and north aspects. But the better aspects, as south, south east, or
north-west, on which are to be trained apricots, figs, nectarines, peaches, and the finer sorts of pears and plums, should, if at all convenient, be faced with brick, or be built of dark whistone.

2462. The basement of the wall should universally be built of durable stone, if it can be obtained, in preference to brick; whether the superstructure be of brick, or of stone in courses. In many cases it is cheaper than brick, in any case the sound-level line to be determined on, the foundation or basement should be sunk at least a yard below it. If for a stone superstructure, it should be thirty inches thick; for a brick and a half brick thick wall, twenty inches; and if for a wall faced with brick, and backed with sandstone, two feet, or twenty-six inches thick, according to the size of the stone; that is to say, the basement should generally be six inches thicker than the superstructure, there being a shelf or scarcement of three inches thick on either side of the wall. If the basement be built with bricks, in order to save materials, the scarcement need not be made more than two inches; that is, the half breadth of a brick or thickness of six inches, allowing four bricks to the basement, and three to the superstructure. (Kensett, p. 114.) The foundation and basement of walls, Neil observes, are often made of common building sand-stone, while the superstructure is brick; and sometimes the back part of the wall is of sand-stone, and the front only of brick or sand-stone. All such in flags, is the best substitute for bricks. Both kinds of materials absent of the branches of the trees being nailed in regularly, and without difficulty. Where brick is scarce and dear, Justice builds the foundation of stone, and lays one course of bricks on that side of the wall which has the best aspect, carrying up the other with stone.

2463. Trellises against stone walls. "Where the walls are of common rubble building," Neil observes, "a trellis of spars is sometimes placed against them, and to this trellis the branches are tied with osier twigs or rope-yarn. This is regarded as a very good plan; but the expense is considerable, as, to prevent the lodging of insects, the trellis must be smooth and painted. The trees thus enjoy the shelter and regular heat of the wall, without being injured by its dampness in rainy weather; and as the wall is not injured by the driving and drawing of nails, there are fewer lurking places for the wood-louse and the snail. The rails of the trellis are made closer or wider according to the nature of the tree to be trained against it. In a few instances in Scotland, walls have been built of different kinds of whistone, chiefly green-stone and basalt." (Edin. Encyc. art. Hort.)

2464. The courses of bricks in kitchen-garden walls, some artists require to be laid horizontally, or on a level; but Hitt, Nicol, and most modern designers, prefer them laid in lines parallel to the surface of the border, which, besides presenting a more agreeable effect to the eye, answers better for lateral or horizontal training, in which, when adopted on such walls, the shoots are laid in parallel to the courses of brick and the surface of the ground. Were they laid in horizontally, there would necessarily be an unsightly blank at the top and bottom of each tree. This is a matter deserving attention, both on account of economy and the effect produced.

2465. Different descriptions of wooden walls have been described (1565.), and one or other of them may be adopted in small gardens, or in particular situations. Nicol affirms (Tat. p. 145.) that fruits may be produced on wooden walls, in as high perfection as on those of brick. He acknowledges them, however, to be less durable. Switzer describes a wooden fruit-wall, made from the boards or sides of "old shipping, which may be had at sea-port towns, and is, indeed, some of the best for fruit of any, not excepting brick walls; for, being pitched and tarred, on account of its preservation before it goes to sea, time and the salt-water, and the different climates through which the vessel sails, so harden and incrustate the planks, that the heat of the sun strikes upon it to a degree not to be borne withal, as all that make voyages at sea can testify. These kind of wooden walls are generally made at half the expense of brick, and will last many years; and you may nail tolerably well into them."

2466. Mud walls. A sort of walls to save bricks are made of mud; "but I do not," says Switzer, "thereby mean such as were in old times made of those coarse materials, though I have, I confess, often seen good fruit on them, but such as they make at this time in Dorset and Wiltshire (dry climates), chalk and mud mixed together, with a proportionable quantity of old hay or straw mixed with it; of which, when the foundations are laid of brick, or stone, or chalk, twofor three feet high, which they often do, it is a very good wall for fruit, not disagreeable, nor of less use and concern for fruit-trees, than stone, brick, or wooden walls."

(Pract. Fr. Gard. p. 300.)

2467. Open railings, or lattice-work of timber or cast-iron, are sometimes used as substitutes for walls. The garden of the Duke of Chandos (Pope's Timon), at Edgeware, was surrounded by a wrought-iron rail, twelve feet high. We have, in the case of a garden of a north aspect, employed an open railing (fig. 426 b) instead of the south wall, and a boarded wall (c) like the fence on the north side. The advantage of this plan is, that the south border (c) of the north wall is sheltered at all times, and the north border and wall of the south rail (c, i) is exposed to the sun during winter and spring, when the trees trained against the rail are
defoliated; while in summer, the same border is shaded by the foliation of the trees, and thereby as well adapted for salading and late crops, as the north border of any opaque wall. This garden had round ends; the semicircular compartments \( f, g \) formed by which were devoted to fruit-shrubs; and the other compartments \( k \), being rectangular, to the culture of the ordinary annual crops: at one end was a building \( h \) serving as a tool-house and watching-lodge.

2468. *Hot or flued walls* have been in use in kitchen-gardens for more than a century; but till lately they were confined to walls with southern aspects. At present, however, it is not uncommon, where all the four walls of a quadrangular kitchen-garden are of brick, to flue the whole of them. The expense of a flued wall is exactly the same as that of a solid one, what is lost in labor being gained in materials; and it is found of great advantage, in cold and late autumns, to apply fires for even two or three weeks, as well to ripen the wood, as the remaining fruit. In spring also, such walls, either with or without some of the different sorts of protecting covers (1492) are found of great use in forwarding vegetation, especially in all the northern counties of England, and in Scotland. Flued walls are certainly not much recommended by Abercrombie, M·Thail, Marshall, or Forsyth, probably from the climate in which these authors gained their experience not requiring such aids. It is acknowledged also, that "this species of forcing is practised by many in a very injudicious way, and much mischief done through error to thousands of fine trees." Nicol, however, the author of this remark, subjoins, that "flued walls are certainly eminently useful, particularly in the northern parts of these kingdoms, and are often necessary to the production of peaches and nectarines in bad seasons." Switzer seems to have been the first to recommend them, giving various plans for hollow-arched and flued walls in his *Practical Fruit Gardener*, some of which had been executed and found to succeed in Lincolnshire, and at Buckingham House. Abercrombie says, "We mention the hot wall without glass work, as among the projects for forcing, an old tried one, but not to recommend it. The expense of glass work is saved by a false economy: the plants are thus excited, on one side, by a strong artificial heat; and exposed to frost and damp violent winds, and heavy rains on the other. Many practical men have found this contrivance calculated to produce an untimely show of blossoms, while the counteracting effect of their situation exposes both plant and blossom to perish. If not applied till the decline of summer, it may do some good in assisting fruit to ripen." (*Pr. Gar.* p. 596.)

2469. *Flued walls for the climate of Scotland* are highly approved of by Justice; and, as they cost no more in erection than solid walls, it may be advisable in many cases to build them, whether steam or smoke heat should be applied or not. The facility with which the former is applied to walls through recent improvements (1561.) is certainly a great argument in their favor. Our opinion is, that in all complete gardens, the whole of the walls should be flued or cellular \( f g \), to admit of the application of artificial heat at pleasure. One boiler and furnace may easily be contrived to supply heat to both the hot-houses and walls.

2470. *Cross walls* \( g \) are introduced where the boundary wall is not sufficiently extensive to produce the desired quantity of fruit, and also to produce shelter to the garden. They are very generally flued walls in all modern gardens north of London, and are not unfrequently wholly or in part covered with glass. The direction of these walls is almost universally east and west, and their height is determined by the surrounding walls to which they are joined. These cross walls, Nicol observes, are not placed nearer to each other than one hundred feet; if they be two hundred feet separate, it is perhaps better.

2471. *Hedges are sometimes introduced instead of cross walls*; but it is obvious they possess only two of their advantages, that of affording shelter and shade. Where they are adopted for these purposes, evergreens, as the holly, box, laurel, spruce, &c. are to be preferred to deciduous trees; as from their surface being, at all seasons of the year, more compact than that of deciduous hedges, they are less liable to harbor birds and vermin. No hedge has
a finer effect than one of shining green holly, decorated with its coral berries. (See Hort. Trans. ii. 354.)

2472. Color of walls. Garden-walls are generally left of the native color of the material of which they are constructed; but they have been also colored white or black, and the latter color is justly preferred as absorbing and refracting more heat than any other, and thereby accelerating the maturity, and improving the quality of fruits. (H. Dawes, in Hort. Trans. iii. 330.) From various trials, it appears that fruit-walls of every description, in the open air, may be blackened with advantage; but under glass, white is preferable, as reflecting light, which is there obtained with more difficulty than heat.

SECT. IX. Ring-fence and Slip.

2473. The ring or outer fence of a garden is generally placed at some distance from the fruit or main walls. The object is to admit the use of these on both sides as well as to obtain a portion of ground in addition to what is enclosed. This fence may either be an evergreen hedge, paling, low wall, or sunk fence, and with or without a wire fence to exclude hares and rabbits. It may be placed at any distance from the walls, according as accidental circumstances, or the purposes to which it is intended to devote the intervening space, may determine. This space is technically called the slip, and, according to M'Phail and most authors, should not be narrower than thirty feet, nor so wide as to throw the plantation for shelter too far off to produce its effect.

2474. The breadth of the slip, according to Nicol, should be at least twenty feet, in order to afford a sufficient border for the trees, and a walk; but it may be as much more in breadth as may be necessary to give ground without the space enclosed by walls for the supply of the family, and it may be enlarged on all sides, or on any particular side, for that purpose. (Kal. p. 6.) The garden, Forth states, should be surrounded with a border, or slip, from forty to sixty feet wide or more, if the ground can be spared; and this again enclosed with an oak paling, from six to eight feet high, with a cheval-de-frize at top to prevent the people's getting over: it will also strengthen the paling. By making slips on the outside of the garden-wall, you will have plenty of ground for gooseberries, currants, strawberries, &c. You may allot that part of the slips which lies nearest to the stables (if well sheltered and exposed to the sun) for melon and cucumber beds; and you can plant both sides of the garden-wall, which will give a great addition to the quantity of wall-fruit. (Tr. on Fr. Trees, p. 294.)

SECT. X. Placing the Culinary Hot-houses and Melonry.

2475. The situation of the hot-houses of a kitchen-garden is as various as the size and form of gardens. In very extensive establishments, as at Kew, and the Royal Gardens, Kensington, a garden or walled enclosure is entirely devoted for this department, including also the framing or melonry. In ordinary cases, however, the culinary hot-houses are either placed against the north wall of the garden, or against one or more of the cross walls. Sometimes they are placed in the slip, which is made wider on purpose, either on the east and west sides of the garden, or to the north, when it is situated on a considerable declivity. Their effect, however, is almost always best when situated within the walls of the garden, either attached or on the north or cross walls. In this way they are sources of greater interest to the proprietor, and come more naturally into the general course of promenade: for it must not be forgotten, that the pleasure or satisfaction derived from even culinary hot-houses, does not wholly consist in being put in possession of certain fruits of excellent quality, (for if so, recourse need only be had to public markets,) but in marking the progress of the trees or plants on which these fruits are grown, in all their different stages; and, as Nicol observes, in being able to say "these are the products of my own garden."

2476. Placing the hot-houses in a range with a directly south aspect, or one inclining to the east, is recommended by Nicol; and it may be here observed, that what is a desirable aspect for the north and best walls of a garden, will also be the best for the hot-houses. By placing them in a range, "there will be an evident saving in the division or end lights, besides the saving of trouble and work to those who attend to them. Being properly arranged according to their different lengths, breadth, and heights, very much beauty and variety may be given to the whole appearance." (Kal. p. 272.)

2477. The hot-houses occupy a considerable part of the south wall, Nicol observes, "in many gardens. In the area behind them are sheds for tanners' bark, rich mould, and other requisites; while there is a cart-access to the doors of the furnaces, and these with the rubbish necessarily attending the operations of forcing, are completely hid from view. In some places all the forcing-houses form a continuous range; but generally the pine-stove and succession pit, being of different dimensions, are placed separately." (Edin. Encyc. art. Hort.)

2478. Culinary hot-houses should not be mixed with houses for plants of ornament. In some old ill-arranged places, the greenhouse and plant-stove, or botanic hot-houses, are united
with those destined for culinary products, and this is very suitable, or is rather a matter of necessity in places on a moderate scale; but where variety and effect are taken properly into consideration, the ornamental or curious productions of gardening will be kept separate from those whose beauty consists chiefly or entirely in their utility. In this way two distinct and strongly marked characters are produced, instead of scenery of a mixed, and as it were neutralised character.

2479. The situation of the melonry is generally in the slip, and where the range of hot-houses are placed on the north wall, and the ground sloping so as to shorten the shadow thrown by this wall in winter when the sun is low, the melonry is with great propriety placed in what may be called a bay of the slip behind the north wall (fig. 427. c). This may almost always be the case when the compost-ground and melonry are placed adjoining each other, as the part most liable to be shaded may be devoted to the former. “The reasons,” Forsyth observes, “for allotting part of the outside slip next the stable for hot-beds for raising melons and cucumbers, are, first, because there will be no litter to carry in within the walls to dirty the walls; secondly, the beds will not be seen from the garden, and lastly, the convenience of carrying the dung, by which a great deal of time will be saved in carting and wheeling. It will be necessary, especially in exposed situations, to enclose the melon-ground with either a wall or paling from six to eight feet high. It was formerly a practice to enclose melon-grounds, with reed-fences; but, although they are tolerably warm, and easily removed from one place to another (being made in separate panels), they are very apt to harbor vermin.” (Tr. on Fr. Tr. p. 295.) In Dalmeny garden, Neil informs us, the melon-ground is situated on the east side of the garden, the garden-wall being extended on the north of it to the same height as the other walls, and flued like the rest of the walls which have a south aspect. The pine-stoves and pits are placed in this melon-ground.

2480. The mould and compost ground, as above suggested, should generally be combined with the melonry, and will be most convenient, if placed between the pits and hot-beds, and the garden-wall on which the range of hot-houses is placed; and thus, when the melonry is placed in the bay behind the north wall, the compost-ground occupies a space that would otherwise be too much shaded for hot-beds or pits.

Sect. XI. Laying out the Area.
In the centre of the garden may be a fountain or basin of water \( (m) \), and in the gardener's house an upper bedroom to overlook the whole. In smaller gardens \( (\text{fig. 429.}) \) the same general plan is adopted as far as their extent admits. Where ornament is to be combined with use, the standard fruit-trees and shrubs may be planted in borders accompanying the walks \( (c, o) \); but where economy of ground is the object, the trees and shrubs may be collected together in compartments \( (a, b) \), and borders altogether omitted.

2482. In laying out the compartments of a garden, Forsyth observes, "you must be guided, in a great measure, by the form and size of the garden; but do not lay them out too small, as in that case a great part of the ground will be taken up with walks and borders. The best figure is a square, or oblong, when the garden is of that form; but if not, they may be laid out in any other figure that is thought to be most convenient." Some of the compartments, in some of our best gardens, Neill observes, are laid out in beds four feet wide, with narrow alleys. So many alleys, no doubt, occupy a deal of room; but advantages of convenience and neatness, in enabling the workmen to clean and gather the crop, without trampling the ground, seem to compensate the sacrifice of space. For currant, gooseberry, and raspberry bushes, the compartments are, of course, reserved undivided; and narrow beds are unnecessary in the case of large perennial plants, such as artichokes or rhubarb.

2483. Laying out the borders. Abercrombie recommends the borders next the walls to be made of prepared soil, "from eight to twelve feet wide, and the same description of soil extended under the walks, in order to allow a liberal width for the roots to spread without impediment. Next to the borders, leave a space for a walk entirely round the garden, from four to six feet wide. Some persons also choose to have a border on the inward side of the walk, for the cultivation of espaliers, and esculents of dwarf growth; others divide the central parts at once into main compartments or divisions. The walks or alleys must be regulated by convenience of access. Where the ground is extensive, the centre should be traversed by a walk, with parallel borders, from which cross walks may branch, if necessary." \( (\text{Pr. Gard. p. 4.}) \) The borders under the walls, Forsyth observes, should, in the inside, be ten to twenty feet wide, according to the size of the garden, to give full liberty to the roots of the trees to spread. There should be a foot-path, about two feet and a half from the wall, for the greater convenience of nailing the trees, gathering the fruit, &c. This walk should be from two to two feet and a half wide, \( (\text{to admit a barrow or barrow-engine for watering the trees,}) \) and covered with sand; or, which is better, coal-ashes, about two or three inches thick, but without any gravel or rubbish below. \( (\text{Tr. on Fruit Trees, p. 294.}) \) The borders for wall-trees, according to Nicol, should not be less than twelve feet in breadth; but fifteen or eighteen feet is not too much. That is to say, the soil should be prepared for these breadth, if it be not naturally good, and perfectly answerable for the different kinds of trees to be planted.

2484. Preparation of fruit-tree borders. It is not enough, Nicol observes, that the upper soil of a border only be improved. The sub-soil must also be attended to, and be laid comfortably dry; otherwise success in the rearing of fruits will be precarious and disappointing. Draining is the basis of every improvement in horticulture, being the basis of improvement in the soil. In this particular case, of preparing fruit-tree borders, it is indispensable. It is also necessary that the roots of the trees be kept out of the sub-soil, if it be of a cankering quality, as till, or corrording sand. This matter has appeared evident to many, and various means have been taken to prevent them from getting down to a bad substratum, at much trouble and expense. I shall here submit a method, the least expensive and most effectual of any, which has been successfully practised for several years.

2485. Forming an impervious bottom to borders. If the sub-soil be wet and cankering, let the border be cleared out its whole length, to the depth and breadth before-mentioned. Lay the bottom in a sloping manner from the wall to the walk, giving it a fall of six or eight inches. Run a drain along by the conjunction of the border and walk, a few inches lower than the bottom thus formed, which shall be capable of completely draining off both under and surface water. It may be a rubble-drain, or a box-drain, according to necessity. Now, lay over the bottom, thus formed and smooth, two inches of good earth, if clayey so much the better, which pulverise and pass the roller
over; then an inch of clean pit or river gravel, which also pass the roller over; another inch of earth, as above, which also roll; and, lastly, an inch of gravel, also, as above. This should be done with the materials rather in a dry state; but now moisten the whole moderately with a watering-pot, and roll until the surface acquires a hard shining consistency. Keep rolling and watering alternately, till the whole becomes firm and glazed, and till the earth and gravel be intimately mixed and incorporated. Thus may a bed be formed for the roots of fruit-trees, much superior to one of stone or brick, and at an expense greatly less; of a nature more kindly, and which no root will penetrate.

2486. Prepared soil for borders should be thrown in, having been previously laid up in a ridge, along the outer edge of the border, before the floor thus made get damaged by wet, or other accidents; and care must be taken that at no future period it be disturbed in digging or trenching the border.

2487. A fit composition for apples, apricots, cherries, and figs is, three fourths lale lightish earth, and one fourth strong loam; being properly composed, and moderately enriched with cow-dung, or a mixture of cow and hog dung, or of cow and stable dung; avoiding the latter, however, if the two former can be obtained, for the cooler dung's answer best for fruit-trees. The average depth of the borders for these kinds should be thirty inches.

2488. A very fit soil for peaches, pears, and plums is, three fourths loam, and one fourth sandy earth, being well mixed, and moderately enriched, as above. The depth for peaches and nectarines may be thirty inches, as above; but for pears and plums, it should not be less than three feet on the average, that is, two feet nine inches at the walk, and three feet three inches at the wall, or thereby. (Kal. p. 153.)

2489. Where the expense of forming proper soils for fruit-tree borders is not incurred, it is necessary to adapt the kind of trees to the soil. On soils, Neill observes, "naturally very light, gravelly, and sandy, peach and nectarine trees do little good; it is better to plant apricots, figs, or vines, which agree with such soils, and, when trained against a wall having a good aspect, will, in the southern parts of the island, afford excellent crops of fruit. On such soils, even espalier and dwarf standard apple-trees are short-lived, subject to blight, and produce only stunted fruit. Next to renewing the soil, the best remedy is to engraft and re-engraft frequently, on the best wood of the trees, giving the preference to grafts of those kinds which experience has shown to be the most productive and healthy in that particular place. In shallow soils, some have been in the practice of making troughs or hollows, and filling them with rich earth, for the reception of the trees; but this is not to be approved of; the roots of the trees will probably be confined to the trough, and it is possible that water may be retained in it." (Edin. Encyc. art. Hort.)

2490. The number and breadth of walks, Marshall observes, "must, in a great measure, be determined by the quantity of allotted ground, exceeding in these particulars where there is room. But few and wide walks are preferable to many contracted ones. If the garden is small, one good walk all round is sufficient; and if long and narrow, the cross walks should not be many: six or eight-feet walks are not too wide for a moderate-sized garden." The middle walk, according to Forsyth, "should be about seven feet, which is wide enough to admit a cart; and the others about three or four feet broad, with a border on each side, five or six feet wide, at least, between the walk and the fruit-trees." "If the garden be very extensive," Neill observes, "the centre is traversed by a broad walk. If it be of the largest dimensions, and possess a cross wall or cross walls, the arrangement of the walks falls to be altered accordingly; a main walk proceeding directly to the door, in the centre of the cross walls."

2491. A walk should always proceed from the main entrance to the main object of the garden. The entrance, as already observed (2386.), should either be in the centre of the south-east or west walls. Where there are hot-houses, it should, if possible, be in the south wall, and from thence a broad walk with suitable borders should proceed direct to the centre of the garden, and across it to the centre of the range of hot-houses. Main walks in square or parallelogram gardens, entering from whatever point, should, in general, proceed to the centre; but in long octagons or irregular gardens, diagonal walks, though they occasion a little more trouble in culture, have a noble effect. It is almost needless to observe, that no main walk ought ever to terminate abruptly, or look to a mere blank, a defect, or an unsightly object. These and various other points of the greatest consequence as to future effect, must be left to the taste of the designer.

2492. Gravel is almost universally considered the best material for walks; but there are various substitutes. "Sand," Marshall observes, "may be adopted for walks, and there is a binding sort of it that does very well; but lay not any of it too thick, as it is the less firm for it. Drift-sand is a good substitute for gravel. Coal-ashes, strewed dunly in the alleys, are better than nothing, as they at least serve to keep the feet dry and clean. If the garden be a strong soil, these ashes (when worn down) should be thrown out of the walks, with a little of the earth, and will prove a good manure for the compartments." (Introled to Gard. p. 35.) A binding sand, Forsyth says, "makes good walks, and they
are easily kept; for when moss or weeds begin to grow, they may be cleaned with a horse-shoe, or scuffled over with a Dutch hoe, in dry weather, and raked a day or two after, by which they will be made always to look neat and clean. I, however, give the preference to sea-coal ashes, which, in my opinion, make the best walks for a kitchen-garden, and they are easier kept than any others, being firm and dry, and cleaner to walk on than sand, especially after frost."

2493. Grass walks may do where gravel is scarce; but the latter is so clearly preferable, that, except for a little variety in large gardens, where there are many walks, grass walks will hardly be made choice of, as they are troublesome to keep in order; and if much used are apt to get bare, and out of level, especially when narrow: they are also frequently damp to the feet. Chamomile has been used also to form green or carpet walks, planting it in sets about nine or ten inches asunder; which, naturally spreading, the runners are fixed by walking on them, or rolling.

2494. Edgings to walks are essential to the beauty and completeness of a kitchen-garden, though, in some cases, verdant edgings are dispensed with. According to Marshall, the borders should have their outer edges, in contact with the walks, made up firm and even. Where the design or intimate communication with the house requires edgings, box is superior to every thing else. In extensive kitchen-gardens, edgings of vegetables, particularly of box, are dispensed with as inconvenient, and apt to harbor slugs. At the same time the margins of the beds and main walks should be kept even and well defined; for this purpose, nothing is more neat and lasting, or better fitted to save trouble, than narrow edgings of brick a single course wide. In the interior compartments, parsley may be sown for an edging; so slips of thyme, winter savory, hyssop, and other aromatic herbs, may be planted; as long as such herbs flourish, or remain ungathered, they form a verdant edging, in character with the kitchen-garden. (Intro. to Gard. p. 5.) Border-edgings, Neill observes, are not in use, excepting for the walks next the walls, and the cross walks in very large gardens; for these, dwarf-box is almost universally employed.

2495. In laying out the slip or exterior area of the kitchen-garden, those parts not occupied as the melonery or compost-ground are disposed of in two borders: the one for fruit, surrounding the wall, and of suitable breadth and composition as to soil; the other next the boundary, of such breadth as the width of the slip allows. The walk between these borders should, in gardens of one or more acres, be made of sufficient width to admit a one-horse cart, to make the circuit of the garden so as to bring in manures, soils, fuel, &c. to any of the wall-doors, for the purpose of being wheeled into the inner garden. The outer border is commonly occupied by low fruit-shrubs, or common kitchen-crops; but in small places, and where the garden is of a mixed character, it is arranged as a shrubbery, and, where Forsyth’s advice is taken, the shrubs are mixed with the more hardy fruit-trees.

2496. A reserve and nursery department should always be formed in the slip, at least in gardens where any thing like beauty or perfection is aimed at. The use of this compartment is to preserve or raise plants, some in pots, others in the open ground, to supply vacancies within the walls. Whatever crop is sown or planted in the garden, a small portion of it should, at the same time, be sown or planted in the nursing department, some in pots, and others in the open ground, by which means, when any blanks occur in the former, they can be filled up from the latter. One part of this department should be devoted to propagating fruit-trees and fruit-shrubs for the same purpose, and also for giving away to poorer neighbors, and for stocking and encouraging cottage and farm gardens.

2497. The best seasons for forming a garden are the spring and summer; but, at all events, at whatever time the operations are begun, they should be arranged so as to be finished early in autumn to admit of planting the fruit-trees and laying the edges of the walks at that season, or very early in the spring.

---

**Chap. II.**

**Of the Distribution of Fruit-trees in a Kitchen-garden.**

2498. To select and arrange a proper collection of fruit-trees, and plant them in their appropriate situations, is the next step in forming a kitchen-garden. This subject naturally comprehends, 1. Wall-trees; 2. Espaliers and dwarf-standards for the borders; 3. Standards for the compartments; 4. Fruit-shrubs. As a point of practice common to each of these divisions of fruit-trees, we may mention that of registering their names either in series (1888.) on a plan of the garden, or by reference to numbers attached to the trees, cut in tallies placed by them, stamped in lead and hung on them, or nailed to the
ARRANGEMENT OF WALL FRUIT-TREES.

2499. Fruit-trees adapted for walls may be considered in regard to the sort of fruit, sort of plant, distance, and planting.

2500. With respect to the sorts of fruit and their distribution on the different aspects of the walls, the first general principle is, that the more delicate species of trees, as the grape, fig, and peach, and those that are planted against the warmest walls; the next is, that the more delicate varieties of the more hardy fruits, as the cherry and pear, are placed against warm walls; and the last, that such varieties of the hardy fruits as it is desired to ripen very early, find a place there. “The best border and wall,” says Abercrombie, “should be allotted to the vine, the peach, nectarine, fig, and apricot: let the vine take the first place for aspect, as it is difficult to bring it to ripen out of doors north of London. Where the peach, nectarine, fig, and apricot cannot have a south aspect, the south-east and south-west are the proper alternatives. Some early sorts of the apricot will ripen on an east or west wall.

The west is the middling exposure, and by no means on a par with the east. The cherry in general may have an exposure looking to any point of the compass, except full north, yet choice early kinds deserve a south border, nor do they attain the climax of perfection without. The morella cherry, the pear in general, the plum in general, the apple in general, and the mulberry will do on any wall; but all late fruit is universally improved in proportion to the goodness of the aspect from the west and east through all the intermediate points to the south, and some of the high-flavored French pears require a fine wall to grow here in perfection. The end of a building is a good site for a free-growing pear-tree; which, if a garden-wall is not uncommonly high, will require a deal of lateral room. A long and high wall is also fittest for a fig-tree. The mulberry, medlar, quince, filbert, currant, gooseberry, and raspberry answer well on espaliers.”

2501. The sorts or varieties of fruit that may be procured at the nurseries are so numerous, as to puzzle an inexperienced person in making the selection. After all, much is generally, and with propriety, left to the nurserymen, who recommends the sorts most in repute at the time. “I have long made it my business,” says Nicol, “to persuade my employers, in the planting of new gardens and orchards, to limit the varieties of fruit, in the firm conviction that I was acting for their interest; for certainly the rage for multiplying them, and of having a numerous collection, has too much prevailed of late. It were better to be contented with a few good kinds that produce well in most seasons, than to plant many sorts (even of those reckoned the finer) for the sake of variety, of which a crop is obtained, perhaps once in three, or in seven years. It is no doubt of very much importance to select and adapt the kinds to the climate, soil, and aspect, and in some cases, a greater variety may be planted with propriety than in others. This matter must be determined by existing circumstances, by the fancy of the proprietor, and by the discretion of the gardener. The following list exhibits a collection, in my opinion, ample enough in any case, though, perhaps, according to better judgment, certain kinds may be substituted for some here named, that may be equally valuable. Certain kinds may also be placed differently with respect to aspect, as may be thought proper, according to the climate and local situation.” Those marked with an asterisk (*) Nicol considers the most valuable kinds, and such as should be preferred in the planting of small gardens, where the walls are of little extent.

Other Sorts.

The Mulberry is sometimes introduced as a wall-tree, and planted on a western exposure.
PRACTICE OF GARDENING. Part III.

2502. The sorts of plants made use of for planting against walls are dwarfs and riders, and these may be of the age of one year from the graft, or they may be several years trained. Dwarfs are understood to be the permanent trees, and riders merely temporary plants introduced to fill up the upper part of the wall. With both sorts it is the practice to make choice of trees that have been two or more years trained; or if they have been moved in the nursery every second year, they may be of five or six years' training, in which case they come into immediate bearing. Some gardeners, however, prefer young plants. Marshall says, trees to be planted against walls, should not be older than two years from the graft or bud. "Much disappointment has been the consequence of planting old trained trees, through their being accustomed, perhaps, to a contrary soil, or by damage done the roots in taking the trees up, and thus, instead of saving time, it has frequently been lost, being obliged, after some years, to be replaced with young ones. But if trained trees are to be made use of, let them be planted as early, and with as full roots as possible, and in a right good soil."

2503. With respect to the age of the plants, Nicol observes, "maiden, or one year trained trees, are to be preferred, especially of apples and pears. Even of the stone-fruits, such will succeed best; though two or three years' trained are often planted. I here allude to the dwarfs. Riders of greater age than dwarfs may be planted, in any case, with propriety; they being considered temporary, and it being desirable to obtain fruit of them as soon as possible." A safe mode is, to plant partly maiden, and partly trained plants, by which means, those which come early into fruit, should they prove bad sorts, may be replaced by others; meanwhile, those sorts which are approved of, will afford an early return for the labor and expense incurred.

2504. The distance at which wall-trees should be planted from each other, depends jointly on the sort of tree, and the height of the wall. For a wall nine or ten feet high, Marshall plants apricots, peaches, and nectarines, twenty feet apart. Nicol, for a wall of twelve feet in height, indicates the following distances:—Apples, eighteen or twenty feet; apricots, twenty to twenty-four; figs, fifteen or eighteen; cherries, twelve or fifteen; nectarines and peaches, twelve or fifteen; pears, twenty-four to thirty; and plums, eighteen or twenty feet. For low walls, of five or six feet:—apples, thirty; cherries, pears, thirty to thirty-five; and plums, twenty to twenty-four feet. The distances at which wall-trees ought to be planted, according to Abercrombie, depend on the general growth of the species, connected with these other things:—whether the individual plant has been dwarfed by the mode of propagation, or is a free grower; whether the species will bear to be kept in bounds by the knife; and, lastly, on the height of the wall: thus, a higher wall is a compensation for a reduced distance, and a lower will make it necessary to increase the intervals. Supposing the wall to be twelve feet high, the following are good average distances for planting the kinds named:—Vines, from ten to fifteen feet asunder, or in vacant spaces between other walls where the distance is less, because the vine bears pruning well, and can always be reduced to the prescribed limits. Peach-trees and nectarines, from fifteen to twenty feet. Fig-trees, eighteen to twenty feet, or more, as the bearers are not to be shortened. Apricot-trees, fifteen feet for the dwarf early sorts, eighteen to twenty-four for the free-growers, as the plant does not bear the knife well. Cherry-trees, from fifteen to twenty feet. Pear-trees, twenty feet, if on dwarf stocks; thirty feet, if on free stocks. Plum-trees, from fifteen to twenty-four feet. Apple-trees, if on dwarf stocks, fifteen feet; if on free stocks, twenty-five or thirty. Mulberry-trees, fifteen or twenty feet. Along the line of the walls only nine feet high, increase the intervals to one fourth as much again; and of walls six feet high, to one half.

2505. The distance of the stem of the tree from the wall at the ground's surface, should, according to most authors, be nine inches; cherries, apples, and pears may be somewhat more; and peaches, nectarines, and vines somewhat less.

2506. The intermediate species between dwarf wall-trees are commonly filled up with riders, or some other temporary fruit-bearing plant. According to Marshall, "the intermediate spaces between peaches, nectarines, and apricots may have a vine, a dwarf-cherry, or currant, or gooseberry tree, of the early sorts, as the smooth green and small red gooseberry, to come in early, and improved in the beauty, size, and flavor of their fruit, by the advantage of situation. But wheresoever grapes can be expected to ripen, there let a young plant or cutting be set, though the space be confined; for the vine, freely as it shoots, bears the knife well to keep it within bounds. If the wall be high, the cherry or plum may be half-standards or riders, which being after a while kept above, will be more out of the way of the principal trees, though dwarfs may be trained so as not to interfere. Some have planted half-standards of the same kind of fruit as the dwarfs, but whichever way is used, let the intermediate trees be pruned away below in good time, in order to accommodate the principals freely as they mount and extend. The better way however is, when the wall is tolerably covered, to extirpate the intermediate trees, as, when large, they impoverish the border, and too much rob the principals.
of nutriment: if taken up well, in season, and pruned properly, they may be planted elsewhere." While the principal wall-trees are making progress, Abercrombie observes, "riders may be introduced between them; these should be confined to sorts which are the quickest in coming into bearing; for else, as soon as the trees become productive, it will be time to remove them. Against low walls, currants, gooseberries, and raspberries may be placed instead of riders. Plant a wall-tree nine inches from the wall, to give the root some room behind; detach or shorten the roots pointing towards the wall, so that the parts left on that side may not be cramped." (Pr. Gard. p. 189.) "On walls ten feet in height or upwards, Nicol plants riders between the dwarf or principal trees, in order the sooner to furnish the wall; but for low walls it is not worth the while, as gooseberries, currants, or raspberries, answer better, and produce fruit more immediately. Riders of all or most of the kinds in the foregoing lists can be had in the nurseries; but they should consist chiefly of apricots, cherries, nectarines, peaches and plums; as few kinds of apples or pears would begin to produce crops before it would be necessary to root them out in order to give place to the dwarfs."

2507. With respect to the mode of planting, the roots of each plant should be trimmed, previous to being planted, by pruning off the points of those bruised in the taking up, and moderately thinning them out, if thought too thick, or too much crowded. This is seldom necessary for maiden trees, but it is often so with respect to plants that have stood several years in the nursery, or that have been trained against walls or pales, and have made strong roots. The roots should be, in some measure, rendered proportionate to the tops; and as the shoots and branches are to be headed down, or to be well shortened and thinned out, it follows that the roots should also be moderately thinned and pruned. In doing this, however, be careful to retain those most promising and best furnished with fibres. The surface level being determined on, prepare the pit so as that the plant may be placed just as deep in the ground as it was before, and not deeper; spreading out the roots and fibres, and carefully bedding them in the compost prepared for that purpose, as hinted at last month. Fill in the common earth, gently tread it round the stem, keeping it a few inches clear of the foundation, and secure the plant from the bad effects of high winds, by tacking it to the wall. Proceed thus, tree by tree, till all be planted. They require no further care till March, when it will be proper to head them down. (Nicol.) Most writers agree in recommending November as the best time to plant on absorbent soils, March for heavy or wet land, and February for medium soils.

Sect. II. Of the Selection and Arrangement of Espaliers and Dwarf-standards.

2508. Espaliers or dwarf-standards are planted in the borders of the principal walks in all complete kitchen-gardens. Besides the value of their fruit, they form a sort of counterpart to the trees on the walls, and add much to the general effect of the garden, by increasing the appearance of design; and much to its beauty in detail by the variety of the blossoms in spring and the fruit in autumn. Some gardeners, however, disapprove of them, or do not consider them of much consequence. "If espaliers are planted," says Marshall, "let them be only fruit of the best sorts, and in spacious gardens, where they may have a good length and height allowed them to grow freely; and let it be resolved to do the business neatly." McPhail disapproves of espaliers, as hurtful to crops of vegetables in the kitchen-garden. Forsyth says, "Espaliers may be planted in some of the borders, in a row along the inner edge." Nicol observes, "Espaliers, if well managed, are both ornamental and useful in the garden, affording a deal of fruit, yet taking up little room." "Of late years," Neill observes, "some have proposed to banish espalier-trees altogether, alleging that they injure the kitchen-garden compartments, by depriving them of sun and air. But in point of fact, they exist in the greater number of kitchen-gardens, and are not likely soon to be laid aside. If they are sometimes injurious, by depriving the plants of air, they are at other times very useful, acting as a hedge in protecting the young crops from the violence of strong winds. Espalier-trees generally produce excellent fruit, the sun and air having access to both sides of the tree; they commonly afford abundant crops, and the fruit is not apt to be shaken by high winds. Further, they tend to hide the crops of culinary vegetables from the eye, and to render the walk of the kitchen-garden as pleasant as an avenue in the shrubbery." Espalier-trees, like wall-trees, may be considered in regard to the kind of espalier-rail, sort of fruit, sort of plant, distance, and planting.

2509. The proper situation for an espalier-rail, according to Nicol, is in the border, by the principal walks, and at three or four feet distant from the walk. They may be placed on each side of the cross walks, if the garden be not very small; but in that case, they would both confine and overshadow the kitchen-crops too much. The railing ought to be plain and neat, four or five feet high, and the upright spars to which the trees are trained, nine inches apart. The posts should be set on blocks of stone, and should be run in with pitch, or, which is a better way, set in blocks of stone, in an iron hose battened into the stone. These blocks, in either case, should be sunk under the surface of the ground.
2510. Espaliers, Abercrombie states, "may be inserted three feet from the edge of the border; but if the ground under the walks has not been prepared, five feet will be better. The stem or head of a wall-tree or espalier must be planted with a little inclination to the fence or trellis; and nailed or tied to prevent the wind from shaking it. Espaliers have the branches trained to an upright superficial trellis, standing detached, and thus bear on both sides. Occupying little room, they drip and shade less than standards, but are more troublesome to manage. While young, they may be rendered in some degree ornamental; but as the plants get old, the most skillful pruning can hardly keep the espaliers fruitful, or prevent them from looking formal, unless the order of bearing will allow the old wood to be freely cut out. Not having the benefit of reflected heat from a wall, there is a distinct motive for training them with a short stem, and with the branches laid horizontally, rather than in a fan-like expansion, and with the highest branches at four feet, or not exceeding six from the ground; for thus they receive a stronger reflection of sun from the earth. At planting, it is easy to set them to the best aspect."

2511. The proper kinds of fruit for espaliers and dwarf-standards, according to Nicol, are included in the following list, in which those marked with an asterisk (*) are deemed the most valuable. For small gardens the apples ought to be grafted on paradise, and the pears on quince stocks.

**Apples.**

*Royal codling, kentish ditto, carline ditto, grey leddington, royal pearmain, ribston pippin, gages pippin, oslin pippin, golden rennet, royal russet.*

**Cherries.**

*May-duke, holman's duke, black heart, white heart, morella, kentish.*

**Plums.**

*Green gage, orleans, moretingham.*

**Pears.**

*Jargonelle, summer bergamot, grey chan, swan egg, moorfowl egg, yair.*

*carrock, warden, scots bergamot, lott-geville.*

*White magnum bonum, blue perdigrine, pimplace.*

**Other Sorts.**

The mulberry, quince, medlar, and service are sometimes introduced as espalier-trees; or dwarf-standards, especially where there is no orchard.

2512. Dwarf-standards are by some preferred to espalier-trees. Hitt and Switzer approve of them, and Forsyth and Marshall prefer them. Abercrombie approves of dwarfs in common with espaliers, but seems, with M'Phail, to prefer them planted by themselves in the compartments. This we conceive to arise from the peculiar notions that many gardeners have, that the kitchen-garden ought to be a mere place of culture, without any of that neatness, or of those beauties which would render it a scene fit to be included in the course of walks for recreation. Where different ideas are entertained, and that order, regularity, and neatness are attempted, which is to be found in an eminent degree in the kitchen-gardens of Scotland, espaliers and dwarfs will be valued as forming the chief furniture of the borders. Abercrombie observes, "Dwarf-standards are raised with low stems, of one, two, or three feet in height, and with round heads proportionately diminished. These are the earliest bearers compared with other standards, and produce large fruit in great abundance for the size of the tree. In small gardens the same benefits and conveniences which recommend the half-standards are attached to these in a superior degree." Marshall observes, that "dwarf-standards occasion less trouble to keep them in order than espaliers, and are generally more productive; planted at eight or nine feet distance, pruned and kept in an easy manner, they make a fine appearance, and produce better fruit and in greater quantities, than when they are in espaliers." (Intro. to Gard. p. 37.)

2513. The sort of plants, as far as respects age, are chosen on the same principle as in choosing wall-trees; but such as are grafted on dwarfting stocks are generally preferred: apples on paradise, creeping apple, or doucin stocks; pears on quince-stocks; and cherries on the perfumed cherry or small wild cherry stocks.

2514. The distances at which to plant espalier-trees, according to Nicol, are, "for apples, on crab-stocks, thirty; cherries, twenty; pears, on free stocks, thirty to thirty-five; and plums, twenty to twenty-four feet. Pears on quince-stocks are planted from twenty to twenty-five feet asunder. Dwarf standard apple-trees, on paradise-stocks, may be planted very closely, as they occupy but little room; they do not require more than ten or fifteen feet.”

Sect. III. Of tall Standard Fruit-trees in a Kitchen-garden.

2515. Though tall standard fruit-trees are more generally confined to orchards, yet they were formerly common in the kitchen-garden, and are still occasionally introduced in the circumferential portion, called the outer border of the slip. They cannot, however, be recommended, on account of the extent of their drip and shade, which renders it impossible to grow culinary vegetables to any degree of perfection, either in size or flavor; and also to the too orchard-like character which they in time give the garden.

2516. According to Marshall, "The fewer standard-trees in a garden the better, as they take up much room, and by their shade prevent the proper growth of vegetables that are any thing near them."

2517. M'Phail considers them as hurtful to crops of vegetables.
FRUIT-SHRUBS.

2518. *Abercrombie* says, "full standards are only or chiefly adapted for orchards and other grounds not occupied by esculents as principal crops. In the interior compartments, some full and half standards may be introduced; but thinly scattered towards the angles of the compartments, not to overspread the ground, nor placed nearer together than forty feet; indeed, many designers of horticultural plantations would restrict the full standards to the orchard and pleasure-ground, as plants cultivated underneath them are apt to suffer from drips." (Pr. Gard. p. 5.)

2519. *Forsyth* recommends their being mixed with other trees in the shrubberies which surround gardens.

2520. *Nicol* concurs in this opinion; and in general prefers standards in the outer border of the slip, or in the orchard.

2521. For the sorts of fruit-trees proper for standards, see Chap. III. on Orchards.

SECT. IV. Fruit-shrubs.

2522. By fruit-shrubs are to be understood the gooseberry and currant tribes, raspberry, cranberry, &c. They are almost universally planted in the walk borders, at regular distances of from six to ten feet. Plantations of them are also formed in the compartments, and in the outer border of the slip. "Some of those useful shrubs, gooseberries and currants," Marshall observes, "should grow in every aspect of the garden, in order to have a succession of their fruits as long as may be. Raspberries may be set in plantations, in rows. Though these shrubs are best by themselves, yet here and there, by the walks, a detached bunch may be kept, or here and there one against a warm wall. Currants, gooseberries, and raspberries," he adds, "do well, espaliered, as to a production of early and fine fruit." *Abercrombie* observes, "Gooseberry and currant bushes may be planted in single rows, in cross rows, or in plantations by themselves:—plant some near the outward edge of the main compartments; others along the borders where there are no espallers; others again in cross rows, to divide large compartments. Raspberries may occupy other borders and compartments." (Pract. Gard. 5. 189.) *Forsyth* recommends planting gooseberries "in a compartment by themselves, or round the edges of the compartments, about three feet from the path. Never plant them under the shade of other trees, as it will injure the flavor of the fruit." "Currants and gooseberries," *Nicol* observes, "are often planted in lines by the sides of the walks or alleys of the garden; but in that way, especially if not well managed, they are generally more cumbersome than useful. It is a better method to plant them in compartments by themselves, and to make new plantations every sixth or seventh year, as young plants are found to produce more handsome fruit, and also more plentifully than old ones. The same thing may be said of raspberries, which produce the finest fruit when young; that is, about the third or fourth year after planting, if properly managed. It is proper to plant some of all the above fruits on a north border, or other shaded situation, in order to prolong the season of them, if that be an object, besides planting them out in compartments, as hinted above. Some may also very properly be planted against vacant places on any of the walls, pales, or espallers. An Antwerp raspberry in particular, and some of the kinds of gooseberries, are highly improved in size and flavor, if trained to a south wall." The cranberry was first introduced as a garden-fruit by Sir Joseph Banks, and is grown to most advantage in bog-earth, kept moist. The margins of ponds, or other reservoirs, in the slip, are good situations for this plant: but when the dewberry, bilberry, and other fruit-bearing bog-earth plants are introduced, we would recommend a border or other compartment in a shady situation, furnished with bog-earth; and to which water could be readily applied, either by the watering-pot, engine, or by means of under-ground channels.

2523. With respect to the sorts of fruit-shrubs, the following list is given by *Nicol*, those to be preferred being marked with an asterisk (*).

<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td>The common red, common white, red antwerp, white antwerp, red cane, and twice-bearing, are all good sorts.</td>
</tr>
</tbody>
</table>

2524. The sorts of plants are commonly such as have been grown two or three years from the cuttings, or in the case of raspberries, suckers of the preceding year. Older gooseberry and currant trees, where they can be procured, should be preferred, to a certain extent, as they bear immediately, and when they grow old can readily be renewed. Raspberries, from their nature, can never have stems of more than a year in age.

2525. In respect to distance, according to *Nicol*, "from four to six feet square, according to the quality of the soil, may be deemed sufficient; that is, in good land, six feet; in middling land, five; and in poor land, four feet."

2526. The mode and season of planting is regulated on general principles. (2071. to 2098.)
Of the Formation and Planting of an Orchard, subsidiary to the Kitchen-garden.

2527. An orchard, or separate plantation of the harder fruit-trees is a common appendage to the kitchen-garden, where that department is small, or does not contain an adequate number of fruit-trees to supply the contemplated demand of the family. Sometimes this scene adjoins the garden, and forms a part of the slip; at other times it forms a detached, and, perhaps, distant enclosure, and not unfrequently, in countries where the soil is propitious to fruit-trees, they are distributed in the lawn, or in a scene, or field kept in pasture. Sometimes the same object is effected by mixing fruit-trees in the plantations near the garden and house.

2528. As to the situation, exposure, soil, and shelter of orchards, most of the observations submitted as to these properties in kitchen-gardens will equally apply to them; but there is this difference, that as orchards are not generally surrounded by walls, and not always under the shade, the surface may be much more irregular; and, in regard to form, it is a matter of no great consequence. Size will of course be regulated by the quantity of produce desired, and nothing can be more simple than the arrangement of the trees which, in regard to position, is almost always that of the quincunx, the distances between the plants being greater or less according to the sorts made choice of.

2529. As to the site of an orchard, Abercrombie observes, "land sloping to the east or south is better than a level; a sheltered hollow, not liable to floods, is better than an upland with the same aspect, and yet a gentle rising, backed by sufficient shelter, or the base of a hill, is eligible. A good loam, in which the constituents of a good soil predominate over those of a hot one, suits most fruit-trees: the sub-soil should be dry, and the depth of mould thirty inches or three feet. Before planting, drain if necessary; trench to the depth of two feet; manure according to the defects of the soil; and give a winter and summer fallow; or cultivate the site for a year or two as a kitchen-garden, so that it may be deeply dug, and receive a good annual dressing."

2530. In a situation much exposed, plant shrubs or wilding fruits, as screens, or as nurses: forest-trees may be planted as an outer screen, but on a distant line, whence their roots will not draw the soil to be occupied with fruit-trees. Where ornamental grounds present a good aspect, as well as prepared shelter, fruit-trees are distributed in them to great advantage.

2531. As to the size of an orchard, Forsyth observes, "it may be from one to twenty acres, or more, according to the quantity of fruit wanted, or the quantity of ground that you may have fit for the purpose."

2532. That soil will do for an orchard which produces good crops of corn, grass, or garden-vegetables; but a loamy soil is to be preferred; though any of a good quality, not too light or dry, nor wet, heavy, or stubborn, but of a moderately soft and plant nature, will be found to answer the end. Shingly and gravelly soils disagree very much with fruit-trees, unless there be loam intermixed. They will succeed much better on a chalk bottom. On such a soil, I have seen roots twelve feet deep, and trees thrive well. The soil should be trenched from two to three feet deep.

2533. The sorts of fruits adopted for orchards are the more hardy apples, pears, cherries, and plums; the medlar, mulberry, quince, walnut, chestnut, filbert, barberry, and some others. According to Forsyth, a complete orchard ought to have, besides apple, pear, plum, and cherry trees, quinces, medlars, mulberries, service-trees, filberts, and barberries; as also walnuts and chestnuts; the two latter of which are well adapted for sheltering the others from high winds, and should therefore be planted in the boundaries of the orchard, a little closer than ordinary, for that purpose. In an orchard for raising crops for sale, Abercrombie says, that fruit is the most profitable for which there is the greatest demand. Apples are first in utility; but pears, cherries, plums, and most other fruits in the subjoined alphabetical list, are acceptable, for dressing in paste, for preserving, or for pickling, as well as in the dessert. According to the extent and nature of the ground, mulberries, medlars, quinces, services, walnuts, chestnuts, and all the sorts which will ripen their produce sufficiently on standards, may be introduced.

2534. The varieties of the common orchard-fruits, recommended by Nicol, are as follows, the sorts marked with an asterisk (*) being preferable:

**Apples.**
- Ribston pippin,
- Gilpin lord,
- Lord of all the Isles,
- Kentish ditty,
- Royal cawdron,
- Knole's ditty,
- Kentish ditty,
- Earl's ditty,
- Royal pears,
- Kentish ditty,
- Royal ditty,
- Kentish ditty.

**Pear.**
- Kentish ditty.

**Cherries.**
- May-duke,
- Holman's duke,
- Black
duke,
- Morello,
- Kentish,
- Large gean.

**Plums.**
- Orriums,
- Damson (black, good),
- Damson (black, ditty),
- White Perigrine,
- Black ditty,
- Blue ditty,
- Blue gean,
- White magnum bonum,
- Red ditty or imperial,
- White Kipple,
- Black ditty,
- Dry d'yor (yellow, ditty),
- Queen claudus (ditty, ditty).

*(Kadens, p. 179)*
2355. The sorts of plants made choice of for orchards are invariably standards, and half-standards, and commonly such as are not more than one or two years from the graft. Abercrombie and Nicol prefer "maiden plants, or such as are only two years from the bud or graft, of all the above kinds, to older trees: having boles or stems of three or four feet in length; the apples being worked on crab, and the pears on free stocks."

2356. The ultimate distance at which apple and pear trees should stand in an orchard is, according to the same author, from thirty to forty feet, less or more, according to the quality of soil and the medium thirty-six feet. In a poor soil, and a bleak exposure, where the trees may not be expected to grow very freely, thirty feet is sufficient; whereas in good soil, and in a sheltered situation, forty may not be too much. Cherries and plums may be planted at from twenty-four to thirty-six feet, according to soil and situation, or above. This is the ultimate distance at which there are to stand clear of one another. But it would be advisable, in the first instance, to plant four trees for one that is intended ultimately to remain; planting the proper kinds at the above distances first, and then temporary plants, which, when the principal plants succeed, will bear early, such as the nonsuch and horticultural apples, the may-duke cherry, and the Crawford and yair pears; or any others better known to produce fruit soon after planting. These should be considered, and be treated as temporary plants from the beginning, and must give place to the principal trees as they advance in growth, by being pruned away by degrees, and at last stubbed up entirely. If orchard-trees be planted among shrubbery, &c. they may be planted at any distance, exceeding forty feet, that may be thought proper; but they should not be planted nearer, otherwise they will too much confine the shrubs. In this case it will not be necessary to plant temporary trees, as the principals will be nursed by the shrubs.

In bleak situations, if forest and other hardy trees be planted among the fruit-trees, it may not be necessary to plant so many (if any) temporary fruit-trees; or these may chiefly consist of the hardier sorts, such as the horticultural apple, the may-duke and morella cherries, and the Scotch gean, which produce fruit the sooner. This method obviates the case of the final distances at which the plants should stand is twenty or twenty-five feet for full standards; of those kinds which reach but a moderate size as trees, and thirty or forty feet for the larger-growing sorts. Temporary plants of such kinds as bear fruit soon may be planted at half the final distances, in order to be pruned down, and at last removed, when the principals require it."

2357. The mode of planting best adapted for standard-trees is unquestionably that of mudding in, and next that of fixing by water (1896. 1897.); one or other of these methods should be adopted, where success and immediate growth is an object, and should be succeeded by staking, panning, mulching, clothing the stems, and watering.

2358. Staking and protecting. "If the stem of a tree is not protected by a wind, the root is prevented from growing, for if it is not protected from the ground it is also opened, so that in winter frost penetrates to the sun, and dries winter. Having set up a firm stake to each high standard newly planted, twist a part of a hay round the tree to prevent it from gailing, and with the remainder tie it securely to the stake." (Abercrombie.) Forsyth and Nicol agree in recommending staking to prevent the trees from being wind-waved. If the trees are to be supported for a time, the orchard be not surrounded by a hedge, the trees should be taken to protect the gardener's four sides, by properly bushing them round with thorns; which I think is the most effectual method, and that least injurious to the trees."

2359. Chie&i001; for a hollow be made round the stem of each tree, a foot or eighteen inches in diameter, and two or three inches deep, according to the extent of its roots. Fill this basin with litter dung, to the thickness of five or six inches, over which sprinkle a little earth just enough to keep it from being blown away. This both nourishes the young fibres, and keeps the ground about them free from heat, when once a week. The dung only is in a semi-circular bed at the base of the autumn-planted trees from the frost of the succeeding winter, and from drought in the summer, Abercrombie directs to "lay mulch about the stem, to the distance of two feet round, and six inches in thickness, and water it in with summer."

2341. Watering. Newly planted orchard must be attended to in respect to watering, whether the ascent and circulation of the sap in the alburnum. This operation should be performed at or soon after planting, and the clothing may be left on till by decay it drops off itself; it is of singular service in very late planting; or when, from unforeseen circumstances, summertime planting becomes requisite.

2342. The best season for planting an orchard is the autumn, as soon as the trees have ripened their wood and dropped their leaves. The work properly executed at this season, the trees will push out fresh fibres the same year, and be ready and able to push out shoots of considerable vigor in spring. When autumn planting is impracticable, the next best is in the beginning of February, or as early as the season will permit.

2343. In a design recently composed, for combining an extensive kitchen-garden with a flower-garden and orchard (fig. 430.), the last surrounded the two former, and served to shelter them. The kitchen-garden (a, b, c) occupied a parallelogram in the centre; the flower-garden (g, h, i), with its botanic hot-houses (g, b, h, i), a semicircular area at the south end; the gardener's lodge (b), gardener's house and garden-offices (c), and nursing departments (p, p), a similar one at the north end; and the orchard (t, r) surrounded the whole. The south and north ends (b, c) were approached by carriage-roads (a, a, a), and the sides by walks (f). The hot-houses were partly in north and south way.
ranges, glass on all sides, for main crops of grapes and peaches \((m, m, k)\), and partly placed against walls \((n, n)\), for more early forcing. The pine-pits and melonry \((u, l, k, n)\), and the compost-ground \((u, u)\), were within the walls, and approached by carts by a subterraneous road from the concealed part of the orchard \((e)\). The hot-houses, pits, and walls were heated by steam from a central tower \((f)\), two ponds \((r, r)\) supplied water to a system of pipes, which distributed it over the open garden, and the hot-houses were supplied from a cistern under the glass roof of the tower \((f)\): a room for eating fruit, or repose \((d)\), occupied a situation which overlooked the whole. The main entrance for the master and his friends was at the southern extremity \((e)\), and that for the head gardener and his operatives at the other end of the garden. \((b)\)

This garden may be considered as composed for effect, as well as for use; and it may be asserted, that the central range of hot-houses, when the grapes and peaches are
in full bearing, will, to the spectator within, present a vault of fruit and foliage, such as has not hitherto been displayed in any British garden.

2544. The subject of cider and perry orchards we consider as belonging more to agriculture than horticulture. (See Encyc. of Agriculture, part iii.)

---

**Chapter IV.**

Of the general Cultivation and Management of a Kitchen-garden.

2545. The cultivation of a garden includes the performance of all those things that are requisite, in order to a reasonable and prolific production of the various vegetables and fruits grown therein. By the management of a garden, is to be understood the keeping it in such order, as that it may not fail in those impressions of pleasure it is calculated to afford. A kitchen-garden, as well as a garden professedly ornamental, may and ought to be agreeable to walk in, as well as profitably cultivated. A gardener may be well acquainted with the culture of individual vegetables and fruits, and yet very deficient in the general cultivation and management of his garden. The following sections relate entirely to general practices conducive to these objects, and they deserve to be carefully studied by the young gardener who aspires at any degree of eminence in his art.

**Section I. Culture and Management of the Soil.**

2546. The soil, Marshall observes, "must be first attended to, always to keep the fruit-borders in heart, and the compartments in a proper state for use, when called upon to receive either seeds or plants. Ground should never lie long without stirring; for the soil of a garden should be in a free, sweet, and rich state, by proper digging, &c. or no great things can be done, as to early, handsome, or well flavored productions. It should be free, that the roots of plants may not be impeded in the quest of food; sweet, that the food may be wholesome; and rich, that there may be no defect of nutriment.

2547. Trenching the vacant ground in a garden does good to all soils in the autumn and winter seasons, and that in proportion to its strength, being indispensably necessary for clays to separate and ameliorate the parts. The light soils may do by being only rough dug, which is a method that stronger soils will be also benefited by. The soil would be still farther improved, by re-trenching, or rough-digging, once or twice more in the winter, if the opportunity offers, particularly if strong or stubborn. Let the ridges lie E. and W. except the ground be a slope, when they may correspond.

2548. The trenching of vacant ground, Abercrombie observes, "should be forwarded as much as possible in winter, and early in spring. By repeatedly exposing a new surface to the action of the frost, a greater quantity of the soil is ameliorated. In every case where it is intended that the ground shall lie fallow any time, it is advisable, in digging trenches, to turn up the earth roughly in ridges; forming, parallel to each trench, a single ridge of the same width, in order that the soil may be the more effectually mellowed, pulverised, and renovated by the weather. These ridges can be expediently levelled, for the reception of seeds and plants; which is a further improvement of the ground."

2549. To conserve the fertility of kitchen-garden soil, the mode adopted by Nicol and practised by the best Scotch gardeners, is the most scientific of any. Nicol observes, that, as kitchen-vegetables do best on what is termed new land, it is a common complaint among gardeners that their ground, by being, as it were, worn out, will not produce certain kinds of vegetables; not that it is poor and hungry, or altogether unfitted to the production of them, having formerly produced them in great abundance, but that the surface has become tired of these crops, in the same way as a field sown with the same sort of grain for two or three years in succession, ceases to produce that grain in perfection. The method which he practised with success is as follows:

2550. First, it is necessary to have a depth of soil from twenty-four to thirty-six inches; in which case it is obvious, that whatever the depth of the natural soil is deficient of, twenty-four inches must be made good by carrying in soil from fields of good quality. Then take three crops off the first surface, and then trench three spit deep, by which the bottom and top are reversed, and the middle remains in the middle. Take three crops off this surface, and then trench two spit; by which the top becomes the middle, and the middle the top. And take also three crops off this surface, and then trench three spit; whereby that which was last the middle, and now top, becomes the bottom; and that which is now the bottom, and was the surface at first, now becomes surface again, after having rested six years. Proceed in this manner alternately; the one time trenching two spit deep, and the other three; by which means the surface will always be changed, and will rest six years, and produce three. Hence there will always be new soil in the garden for the production of wholesome vegetables; and hence also will much less manure be required, than when the soil is shallow, and the same surface constantly in crop. He adds, that he would not advise the soil to be more than three feet deep, as the surface might be buried too deep from the action of the weather, and influence of the sun. Where the soil is only so deep as to allow of trenching two spit, by trenching every third or fourth year the ground will rest half its time; and if judiciously managed, and cropped in proper rotation, wholesome vegetables may be
produced on it for many years successively. It is not intended that the whole garden should be trenched over the same season, *one half, or a third part at a time may be more advisable, and also more convenient." (Kal. p. 16.)

**Sect. II. Manure.**

2551. *When manure is applied the ground is not to be glutted with dung; for, as Marshall observes, "a little at a time, well rotted, is sufficient, so that it comes often enough, as opportunity and the nature of the cropping may dictate. It is indeed a sort of rule with gardeners, that ground should be dunged every second year; but circumstances may make more or less of it necessary, and rules should never be indiscriminately applied.* If dung is pretty well reduced much less will do, and let it not be buried too deep; but if it is otherwise, lay it low, to be dug upwards another time, when it is more consumed. It is an excellent way of manuring, where the superficial soil is much exhausted, to dig slightly, and spread over rotten dung, late in autumn, in the winter, or early in spring, and so let it remain, till the ground is wanted, before it is dug in; which should, however, be slightly dug before the manure is put on, or forked in a little afterwards. This method is particularly to be recommended where crops of onions, leeks, and such superficial rooting plants are to be.*

2552. *Dung used in great quantities, and lying in lumps, harbors worms, grubs, and insects, and makes plants grow too rampant and rank-flavored. Carrots it rankers, and it disagrees with many things; is apt also to make the ground parch, and burn the crops sown upon it in a hot summer. On these accounts some persons have been induced to dress their gardens only with rich fresh earth; which, if they do not overcrop, will do very well, being accompanied with good tillage; which alone is of much use, and is essential to due cultivation. Vegetables are always sweeter the less dung is used, and little need be used when the natural soil is good and deep; for the earth may be so dug, that what is at the top one year may be at the bottom the next: which is a manoeuvre evidently advantageous, as a good part of the strength of the top soil washes downwards. The method just recommended, of letting dung lie on the surface for a time, is good also, as it abates the rankness of it. Lime sweetens.*

2553. *The periods for applying manures necessarily depends on the soil and the mode of cropping. If the original soil be poor, it may require aid from dung every year; but, in general, the compartments in which annuals and biennials are cultivated will want to be thus recruited at least once in two years, when the last autumn crops are off the ground. Beds occupied by perennials cannot sometimes receive any material accession of new earth or compost for a number of years; and therefore, when the stools are worn out, the repairs of the soil should, in proportion, be substantial, and go deep. Dung is fit to manure beds for receiving many sorts of plants, when it has lain in a heap from three to six months, and is beginning to be well rotted. But for particular purposes, it should lie from one to two years. Apply it for annuals, two or three inches thick; for perennials that are to stand long, six or eight inches thick; spreading it equally, till the bed into which it is to be dug is covered; then trench it in a moderate spade deep, that it may be within easy reach of the roots of the plants. In preparing ground for perennial stools, a portion of the dung should be deposited six inches deeper.*

(Abercrombie.)

2554. *Manures are to be applied either as simples or compounds; but the latter method Nicol considers the most eligible. He agrees with Jethro Tull in stating, that if they have not undergone a proper fermentation, their effects are, giving a rank and disagreeable flavor to fruits and vegetables; and if an immoderate quantity be applied, of producing a considerable degree of unwholesomeness, and tainting the juices of all plants.*

*A mixture of stable-dung, sea-weed, lime, and vegetable mould, which has lain in a heap for three or four months, and has been two or three times turned during that period, will make an excellent manure for most kinds of garden-land. Also, cow-dung, hog-dung, and sheep-dung, mixed with soot or with wood-ashes. Pigeon-dung and vegetable mould, well mixed, will also make an excellent manure for heavy land; or even for lighter soils, provided the pigeon-dung be used sparingly.*

*Neats-dung and hog-dung, slightly fermented, are very fit and rich manures for light hot soils. For those of a dry, absorbent nature, none answer better, or last longer; by reason that they retain moisture for a greater length of time, and also ferment more slowly than other dungs.*

*Pigeon-dung, lime, soil, ash, &c. should never be applied as simples; the quantity required being comparatively small, and the regular distribution of them difficult, without the admixture of other matter. Provided generally be applied to compost of good earth, turf, or sward, or of cows, or other dung of a cool nature; applying them in quantity according to the cold or the hot nature of the soil to be manured, allowing the compost a sufficient time to incorporate, and mixing it thoroughly.*

*Stable-dung, if used as a simple, should not be applied in too rank a state, nor should it be much fermented. It should generally lie in a heap for four or five weeks; during which time it should be turned over once or twice. A ton of it in this state is worth three that has been used in the hot-bed, and is a year old. This manure, and indeed dung of any kind, when applied as a simple, should never be carried from the heap to the ground, till it is to be dug in; as, by exposure to the air, part of its virtues evaporate, and it is the less effectual.*
Sea-weed should be applied instantly after landing. If used as a simple, it is even greater than the above; as it instantly corrupts, and its juices flow downwards, and are lost. If this manure be used as a compound, the heap in which it is compounded should be more frequently turned on its account; that none of the juices may be lost, but that the other part of the compost may absorb them.

Horse-dung, and the dung of sheep, deer, and of rabbits are most eligible for cold wet soils; and all these, or any of these in compost with lime, will be found beneficial. For such soils also, a compost of coal-ashes, pigeon-dung, and lime; or of wood-ashes, whin-ashes, fern-ashes, and stable-dung; or of deer-dung, rabbit-dung, soot, and burnt sward, will make a good manure.

Manures are to be applied in quantity according to their quality. Hence the dung of pigeons should be applied in much smaller proportions than that of horses, it containing a greater quantity of volatile salts; and so the ashes of vegetables containing a portion of fixed alkaline salts, being more powerful, are to be applied in still smaller quantity. So also, lime being the most powerful of the calcareous kind, should be applied, in ordinary cases, in much smaller quantity than marl.

Vessels would may either be used as a simple, or be used as a compound, and may be applied with equal propriety to all soils. None can be hurt by it in any degree, since almost every plant will grow luxuriantly in it alone, without the aid of any soil or manure whatever. It seems to be the ambrosia, and the dunghill drinking the nectar, of vegetable life. The latter, however, if too freely indulged in, is rather of an intoxicating nature. (Kab.)

2555. Where economy, rather than the flavor of culinary crops, is an object, recent dung is unquestionably to be preferred (1156.), and, in fact, is so by most market-gardeners: John Wilmot, an extensive market-gardener at Isleworth, bears testimony to this fact. A given weight of recent stable dung, he says, will not only go farther than the same weight of rotten dung from old hot-beds; but will serve as a manuring for the succeeding crop, which, with old dung, is not the case. (Hort. Trans. iv. 55.)

Sect. III. Cropping.

2556. A change of crops is founded on the generally acknowledged fact, that each sort of plant draws a somewhat different nourishment; so that after a full crop of one thing, one of another kind may often be immediately sown. “Nothing tends more to relieve the soil,” Abercrombie observes, “than a judicious succession of crops; for plants of different constitutions not only strike to different depths, and in different directions, with their roots, but the terminal fibres or feeders of the roots appear to take up separate and peculiar constituents of the soil, and to be indebted for support to some property imparted by the earth in very different degrees. The duration of the vegetable, its short or protracted existence, is a great cause of diversity of effect as to the quantity of aliment drawn from the soil. Another mark of distinctness in constitution is the character of the root, as it may be fibrous and tender, or fibrous and woody, — or bulbous, or tuberous, — extended or compact; another, the form and magnitude of the herb, and the proportion of fibrous or ligneous substance in the stem and branches. A fourth index of a separate nature is the succulence or hardness of the leaves, and the quantity of pulpy or farinaceous matter in the parts of fructification, — as the leaves may be the edible part, before the plant is matured; or the seed-vessels, as in pulse, may hold the produce for the table; or the esculent part may consist of fruit-enclosing seeds. To apply this practically: — we will suppose a strawberry-plantation requires to be renewed; and the stools seldom continue fully productive more than three or four years; — instead of introducing young strawberry-plants into the same bed, entirely eradicate the old plantation, and let it be succeeded by a crop of beans, or of some other esculent as different as may be in constitution and habit. In the same manner, let the new plantation of strawberries follow some light crop which left the ground in a good state, or which allowed it to be trenched and followed for an interval, whether it were an annual or biennial. It is a rule, from which only extraordinary circumstances can warrant a departure, never to plant a new set of perennial stools on the ground whence a plantation of the same or a similar species, having worn itself out, has just before been removed. On the contrary, crops which strike deep, and occupy the ground long, should be succeeded by plants which pierce but a little way under the surface, are drawing in the least degree, and soon come off from the short term of their vegetable life.”

2557. A studied rotation is advisable, in all cases, according to Nicol; so as that no crop of the same class may immediately follow another. To facilitate this measure, the kitchen-ground should be divided into a number of portions, and a journal or note-book should be kept, with a reference to their numbers. In this journal, whatever relates to their cropping, manuring, trenching, or following should be recorded, for reference and guidance as to future cropping. Nicol, while practising as head gardener at Raith, Wemyss Castle; and other places, kept a regular journal of this sort; he published it in his Kitchen Gardener in 1802, and he tells us, in 1816, that it had been approved and adopted by many practical gardeners. (See the model, 2345.)

2558. By planting out currants, gooseberries, and raspberries in compartments, instead of growing them in single lines, particularly if these be properly managed, an opportunity of changing crops might further be afforded; as these should not stand longer than seven or eight years together, before the plantations are renewed.

2559. Strawberry-plantations, under proper management, should be renewed every four or five years; and thus likewise might an opportunity of changing crops be afforded.
Also, by the renewal of artichoke and asparagus plantations, which should be done every seven or eight years. In managing all the above-named articles on a large scale, new plantations should be made every year, to a certain extent, which would throw a certain proportion of ground regularly into the rotation.

2560. Esculents might be cultivated in classes, and thus a sort of rotation, though not very complete, might be produced; and the brassica tribe, the leguminous family, the tuberous or carrot-rooted kinds, the bulbous or onion kinds; and the lighter crops, as salads and herbs, might succeed each other.

2561. Close crops, as onions, leeks, carrots, &c. are conveniently and neatly cultivated in beds of from four to five feet widths, with alleys of a foot to eighteen inches between them.

2562. Resting garden-ground. Market-gardeners, Nicol observes, who are generally good managers, and must of necessity make the most of their ground, in order to maintain their families, and be able to pay high rents, have found out the utility of resting their land, and of following a regular rotation in cropping it, at least in the culture of the principal articles, and as far as the nature of the thing will admit. The best managers sow out a portion of their ground every season in grass, clover, or barley, which is used as green food for their horses and cows. Very generally the barley is sown along with the clover, merely to nurse and shade it, being cut down and not allowed to ripen. The clover is sometimes dug up after the first season, if land for market-crops be scarce, but more generally it is allowed to lie a second year. By good managers, the ground is never sown down in a hungry state. Land that has been under esculent crops for many years together, and is, perhaps, glutted with manure, may be cleansed, as it is termed, by a scouring crop of oats, wheat, or rye, which, if thought necessary, may be repeated. If trenched to its full depth afterwards, it will again be fit for the production of culinary crops in great perfection.

2563. The seasons proper for furnishing the ground with every particular vegetable should be well attended to, that each may be obtained as early as its nature will permit; and of the seeds and plants we use, care must be taken to procure the best of the kind, lest after all the trouble of cultivation, disappointment as to vegetation or quality should ensue. The principal time for sowing and planting the articles raised in the kitchen-garden falls in the spring months. It is necessary to lodge some sorts in the ground as early as January; but February, March, and April are the months in which the principal supplies from summer crops are provided for. From April till September, and even October, many sorts are sown and planted, in smaller portions, for successive crops. Particular hardy esculents are also sown or transplanted principally in autumn, for a supply as well in winter as in spring and early in summer. Other kinds are inserted occasionally as late as November and December, to stand wholly over the winter, in rising growth, for early crops and for main crops the following summer; such as peas, beans, cabbages, and cauliflowers. To obtain early crops of favorite esculents which are more tender, several kinds are sown and planted in hot-beds in winter and spring.

2564. The quantity sown and planted is to be determined jointly by the demands of the family and the portion of ground that can be spared: but it should be always a rule, to sow and plant more than probably enough for the family, as more may happen to be wanted than expected, and a cross season or other accident may occasion a failure. As exact rules cannot be laid down, the exercise of a little judgment will be necessary, in order to proportion crops alike; for to have too much of one thing, and too little of another, is disagreeable and discreditable. Respect should be paid to the natural duration of crops, some going off soon, and others being lasting, and that too according to the season they are propagated in. The pea requires the greatest breadth of surface; and next to this the cabbage tribe. The spaces for asparagus, artichokes, strawberries, sea-kale, &c. are in some degree fixed from the comparative permanency of these crops. Pot and sweet herbs require the least space, and ascending from these to breaths necessary for the pea and cabbage tribe, the proportions are as various as the kinds to be grown; and these can only be acquired properly by experience, and observation of what takes place in different gardens.

2565. Seeds and plants should be adapted as much as possible to the soil and situation which best suits them; for in the same garden some difference will be found, not only as to sun and shelter, but the earth; as some will be richer, some poorer, some deeper, some shallower, and some perhaps heavier, some lighter, in due attention to which, advantage is to reaped. (Marshall.)

2566. The ordering of seeds from the seedsman is generally a matter of some difficulty to the young gardener, and Abercrombie is almost the only author who has endeavored to remove it. The information afforded by his work, entitled The Seed Estimate, will be found in the Horticultural Catalogue; where under every culinary vegetable raised from seed, will be found the quantity, either stated in weight or measure, requisite for a certain space of ground; and this space generally that which is deemed sufficient for a considerable garden.
THINNING.

Sect. IV. Thinning.

2567. The thinning of seedling crops, Marshall observes, "should be done in time, before the young plants have drawn one another up too much. All plants grow stronger, and ripen their juices better, when the air circulates freely round them, and the sun is not prevented from an immediate influence; an attention to which should be paid from the first appearance of plants breaking ground. In thinning close crops, as onions, carrots, turnips, &c. be sure that they are not left too near, for instead of reaping a greater produce, there would be a less. When they stand too close, they will make tall and large tops, but are prevented swelling in their roots; better to err on the wide side, for though there are fewer plants, they will be finer and better flavored."[1]

2568. Thinning the leaves of fruit-trees. "The leaves," Abercrombie observes, "have too essential an office as organs of growth to the entire plant, to be lightly parted with; and where the climate is not deficient in heat, compared with the habitat of the plant, or the portion of the year in which its season for vegetating falls, their shade is more likely to be serviceable than detrimental, even in the last stage of fruiting. Thus, cherries, raspberries, strawberries, currants, and other species whose full term of fructification is more than comprehended in our summer, reach perfect maturity, and acquire the color proper to each, though ever so much covered with leaves; whereas for those kinds which ripen with difficulty here, because the direct rays, and most intense reflection of the sun, is scarcely equal to the heat in the shade during the full summer of their native climate,—it is proper, when the fruit has nearly attained its full size, and is naturally losing its absolute greenness, to remove some of the leaves which shade it too much. Were the leaves thinned sooner, it would prejudice the growth of the fruit; and should they even now be swept off unsurprisingly, the growth of the year's shoots might be arrested. The leaves which cover the fruit, whether peaches, grapes, late pears, or other exotics, must be removed gradually; that is, at two or three times in the course of five or six days; otherwise the unusual full heat of the sun darting upon the fruit, would occasion the rind to crack."[2]

2569. Nicol says, "My practice has been, as the fruit begin to color, to pick off every leaf that may overhang them; thus very much enhancing their beauty and flavor. In late seasons, if the leaves of wall-trees hang longer than usual, they may be brushed off, in order to let in the sun and air the better to ripen the wood. This brushing, however, should be cautiously performed, never brushing much at a time. The leaves should not be forced off violently. Some use a common stab-broom for this purpose; but a better instrument is a hazel, or strong willow withie, or a small smooth cane. The shoots from which the leaves are to be displaced, should be gently stroked upwards, and outward; but never the reverse way, else there is danger of hurting the buds. Trees exposed to the wind seldom require this care; but sometimes spaliers may, and if so, the same course is to be pursued as above."[3]

2570. Thinning stone-fruits. Thinning the over-abundantly set fruit on apricot, nectarine, peach, and plum trees, is a necessary duty; as many of these, in good seasons, set more than they can nourish or bring near to perfection. This thinning, however, must be cautiously performed, and by degrees. If the trees have set their fruit very thick in particular parts only, such parts should be moderately thinned out now, and the other parts not yet. But if the fruit be very quickly set all over the tree, let it be generally thinned off to half its extent at this time; deferring the final thinning till the stoning be over; that is, till the shells be quite hard, and the kernel be formed. For most trees, especially those anywise unhealthy, drop many of their fruit in the time of stoning; so that the thinning had better be performed at two or three different times; always observing to reserve the fullest, brownest, and best-formed fruit. Stone-fruits must be again looked over in June, and a more few fruit thinned off where too thick; and the final thinning must take place in July, when the stoning of stone-fruits is over, and previously to their beginning to swell off for ripening. (Nicol.)

2571. With respect to the quantity or number of fruit proper to be left on a tree, "much," according to Nicol, "must depend on its size and strength, and whether it be full grown, or be yet in training. A full-grown tree, in a healthy state, may be allowed to produce considerably more than one in a weak condition. And if a tree yet in training, that is, one not having filled the space allotted to it, be allowed to ripen all the fruit it may set, its extension will be much retarded in consequence. On the More-park apricot, and the larger kinds of peaches, in a healthy full-bearing state, a fruit to every foot square of the superficial content, or surface of the tree, may be taken as a good medium; that is to say, a tree covering a space fifteen feet by twelve, may be allowed to ripen about two hundred fruit. The smaller kinds of apricots and peaches, and of nectarines in general, may be allowed to produce a third part more, if in a healthy state. The larger and better sorts of plums may be thinned in proportion, and according to their sizes; and may be thinned out to from three to six inches apart, if on the shoots of last year, or so as to hang quite free of one another, if on spurrs. I am aware, that many will think thinning to this extent an extraordinary measure; but I would have such be convinced of the propriety of doing so, by comparison. If they have two trees of a kind, both healthy and well loaded, let the one be thinned as above, and allow the other to produce as it has been wont; or thin it even to half the extent. It will be found, that the tree fully thinned will produce an equal, if not a greater weight of fruit, and these incomparably more beautiful, and higher in flavor. Observe, the comparison must be made the same season, else it would not be fair; as the size and flavor of the fruit might be very different, according to the goodness or badness of the weather in different years."[4]

2572. Apples and pears should be moderately thinned, and good account would be found in the practice. This should be done when the fruit is about half grown, or when all ap-
PRACTICE but either let for and and gum nailing the from wall-tree fruitful into spurs, doubtful, laying the destroyed, the summer on the first case down afford to any kind of bearing, the fruit-shoots; bearing, the fruit-buds; the fruit-shoots, and fruit-bearing, of course is most commonly expedient on the peach-tree, or nectarine, or apricot. If the first shoots happen to be unexceptionably placed for beginning the figure, instead of heading down the stem, cut these into two or three eyes. On wall-trees and espaliers, rub off the fore and back wood-buds.

2575. Seasons for pruning newly planted trees. On all trees during the tender stage of infancy, spring is the fittest time of pruning, even for wood, and for proceeding in the formation of a head, as successive sets of new branches are yearly obtained by shortening the last. Something may also be done in summer to promote this object. If between the end of May and the end of June, a pair of shoots have not-started as desired, one on each side from a stem headed down, or from the mother branches shortened; and in lieu of such, one solitary shoot has arisen, or two, both on one side, or not equally proper to be retained, the desired end may yet be attained, and a season saved. Pinch down the solitary shoot two or three eyes: this will force out new shoots in the course of summer. In the case of two shoots, one of which is evidently unfit for beginning the head, take off the one rejected without delay, and pinch down the other to two or three eyes. Of two shoots on the same side equal in regard to strength and direction, to preserve the lower on wall-trees and espaliers, rub off the fore and back wood-buds.

2576. Summer pruning of trees in bearing. The buds and shoots to be preserved claim the first attention; for if the precious germs of future fruit or wood are carelessly destroyed, the work of reproduction is difficult and tedious: whereas the removal of spray not of service as branches or bearers, though necessary to prevent confusion, and to strengthen the plant, is to be conducted in subservience to the vital object of fertility. For the present retain all the fruit-buds and fruit-shoots, and as many well placed wood-shoots as will afford a selection for winter pruning: but rub off ill placed and superfluous wood-buds, as they can be certainly discriminated, or after waiting till appearances are no longer doubtful, pinch off the shoots from such wood-buds before they are above three inches long. In some kinds, to avoid the destruction of wood-buds, or the germs of fruit-spurs, the disbudding ought to be postponed until the wood-shoots can be distinguished from spurs, and pinched off without injuring the fruit-buds. The species which alternately produce spurs on the one-year-old shoots, are, the apple, pear, apricot, cherry, and plum. The peach and nectarine rarely emit spurs. While you avoid displacing infant spurs on plants which bear on such, be as careful to discourage the wood-buds and shoots on old spurs, for shoots from these are cumbersome and unprofitable. If any spray that wants displacing has got woody, use the knife, lest the bark of the mother branch be torn.

2577. The mode of bearing, and the duration of the bearers, is the first thing to be adverted to for regulating the proportion of new wood to be retained. Thus, in the kinds which bear on spurs, a less quantity of advancing wood is necessary for future supply, according to the time that a bearing branch continues in fructification, but in the fruit-shoots on some of these kinds are two, three, four, and even five years in coming into bearing, the difficulty of excising a proper eye is increased. On the sorts which bear on the shoots of last year, although a great reserve, and constant annual succession are wanted, it is more easy to suit the provision to the expected vacancy. In both classes, the leader to a stem yet under training as a wall-tree is to be carefully preserved: also a surplus number or buds to the right and left must be suffered to sprout, till it can be known whether shoots will spring at the desired places; and afterwards a selection from these for forming the tree: further, the leading shoot to each side branch should be always left, if the limits admit. Well placed shoots, between the origin and the extremity of a lateral, are to be retained in pairs, until a good leader has sprung, and is sufficiently established to be laid in; when they are to be cut away close, unless a vacancy requires their permanent cultivation. As the new laterals fit to be preserved extend, lay them close to the wall in a straight easy direction, at a convenient average distance; nailing them farther onward as the extremities want support.

2578. Three revisions are included in a summer's pruning; one beginning at the end of April, another in July, and the third in September: all which have a preparatory respect to the winter pruning. Stone-fruit trees, if much wounded in summer, are apt to gum; so that if superfluous shoots have not been removed before they get woody, it is best to defer the retrenchment of these to the winter pruning. A weak tree is strengthened by reducing its spray; let it, however, be low and compact, rather than naked. To
keep a luxuriant tree full of wood tends to make it less rampant: but a crowded intricacy is to be avoided; for the air stagnates in a thicket of spray and foliage, while the sun cannot penetrate it: hence the new shoots grow long-jointed, and do not ripen thoroughly; and the blossom-buds forming on the bearers for the following year will be fewer and less plump. All the shoots rising after midsummer are to be displaced, unless a vacancy cannot be furnished without reserving some of them; or unless the excessive luxuriance of a plant makes it proper to cut it as little as possible, and to let the sap expend itself in numerous channels. The spring shoots laid in are generally to be preserved at full length, as far as the limits will permit, until after the fall of the leaf; because to stop them in summer would cause them to shoot from almost every eye, and fill the wall with spray; hence, when a vacancy wants several branches to furnish it, it is a good resource to shorten a strong contiguous shoot to three or four eyes. This is the exception to the rule.

2579. Winter pruning of trees in bearing. Now a final selection is to be made from the last year’s shoots retained as candidates during the summer. On established trees which have fully ripened their shoots, and of which the young wood is not succulent, and therefore susceptible of injury from frost, there is a wide latitude of time for the capital or winter pruning, extending from the fall of the leaf to the time of the sun’s rising, or just before. To prune in autumn strengthens a plant, and will bring the blossom-buds more forward: to cut the wood late in spring, tends to check a plant, and is one of the remedies for excessive luxuriance. At the opening of spring, the blossom-buds can be certainly distinguished, which is a great guide to the judgment in many critical cases; but on the other hand, if the blossom-buds get much swollen, they are liable to be bruised or knocked off, in the various operations of untacking, cutting, and re-nailing the branches. Supposing the common course of winter pruning to be divided into three periods—autumn, the cold months of winter, and the beginning of spring—the plants to be excepted from the first two, are, uniformly the fig, when not in a fir-clothing, the vine for the most part, because the autumn is seldom hot and fine sufficiently long to ripen the year’s shoots. Some except the peach and nectarine from the middle period, but not from the first; because they say, that if a severe frost happen immediately to follow the pruning, the points of the unripened shoots, and particularly the wood-bud next to the cut, are generally so much hurt, that there must be a second shortening, farther in than was intended to furnish these shoots with leaders.

2580. The number of good shoots to be retained is limited by the character of the tree, the size to which the fruit grows, and the compass to be given to the head. The branches of a wall-tree may be from five to ten inches in diameter, according to its strength and the size of the fruit. Of fruit-shoots those are the best which are short-jointed, and show a competent number of blossom-buds, and on which the series of blossom-buds commences nearest to the origin of the shoots, especially on that class which must have the bearers annually shortened. Spongy or disproportionately large and gouty shoots are bad alike for wood and fruit; bat long shoots for fruit may be retained, if the buds are well defined; and the best shoots for fruit may incline to slenderness, if not wiry and sapless; disproportionately large shoots are seldom fruitful. In choosing large supplies for wood, other things being equal, the lowest new branches, or the leaf buds nearest the base of a branch, or of a thicket of thongs, are the best. Begin at the bottom and middle of the tree; keep these furnished without intricacy; and the extremities will be easily managed. Such shoots as are preserved, whether to come in immediately as bearers, or to furnish naked parts in the figure, or future supplies of wood, are to be treated according to the kind of being.

Class bearing on distinct branches. On those species which bear at the ends of the branches, or on spurs for several years in succession, the leading shoot of a fruit-branch is always to be retained, on a double account; and the fruit-branches are not to be shortened where they do not exceed the assigned limits for the tree; because, if stopped, these would send out strong wood-shoots, where blossom-buds or fruit-spurs had otherwise been produced.

2581. Exceptions to this rule: on young trees under training, to be furnished with a head, shorten the branches until the designed figure is complete; again, though a tree be established, occasionally shorten a branch to bring out wood to fill a vacancy. The surplus of the last year’s shoots, which would crowd, or disfigure, or too much weaken the tree, or occupy it without promise, are to be cut out clean to the parent branch; also cut away any old branches which appear decayed, or of which the spurs begin to get barked. Finally, take off close the naked barren stumps left at previous amputations.

2582. Class bearing on last year’s wood only. On trees which bear on the last year’s wood, there is a necessity for annually shortening alternate divisions of the branches, in order to provide a supply of new shoots for bearing the next season. We prune the longer branches of a luxuriant plant, and the shorter of a sterile one, so that the strongest part of the tree is to cut in and retain wood which would crowd, or disfigure, or too much weaken the tree, or occupy it without promise, are to be cut out clean to the parent branch; also cut away any old branches which appear decayed, or of which the spurs begin to get barked. Finally, take off close the naked barren stumps left at previous amputations.

2583. Deciduous. There is a small anomalous class which bears frequently on spurs of several years’ continuance as well as on annual shoots, but chiefly on the latter. Shoots of this class are to have a mixed treatment, preserving the fertile spurs as much as may be. Having finished pruning a wall-tree, lay in the branches and shoots directly; tacking them in a next manner to the wall or trellis. (Aceracerum.)

2584. Winter pruning to be revised. Revise the pruning when a sufficient time has elapsed to see it with another eye; or when the expansion of the blossoms decides the
competition between probationary fruit-shoots which have been laid in too close. In
those stone-fruit trees which bear on the last year's shoot, such as the peach and most
kinds of the apricot, it is particularly necessary to revise the winter pruning at the
time of blossoming; because, if on any branch the blossoms are observed to have been
spoiled either by gum, by blight, or spring frost, that branch is quite useless as a bearer,
and unless it has made some shoots which may prove bearers the following year, is to
be entirely cut away: but if the blighted branches have made well placed shoots, shorten
them to these. (Abercrombie.)

2585. Methods of training. The two principal methods of training wall-trees which
are followed in this country, Neill observes, are called the fan and the horizontal modes.
In the former, the branches are arranged like the spokes of a fan, or like the hand opened
and the fingers spread. In the other way, a principal stem is carried upright, and
branches are led from it horizontally on either side. The Dutch style consists in taking
a young tree with two branches, and leading these horizontally to the right and left, to
the extent, perhaps, of twelve feet each way, and in then training the shoots from these
perfectly upright to the top of the wall. This is now seldom practised here, excepting,
perhaps, with fig-trees, or white currants. In some cases, a few of the wall-trees are
trained in a stellate form, the stem being led upright for about six feet, and then some
branches trained downwards, others laterally, and others upwards. When walls exceed
seven feet in height, the best gardeners seem to concur in giving the preference to the
fan training, variously modified: in this way they find that a tree can much sooner be
brought to fill its allotted space, and the loss of a branch can much more easily be sup-
plied at any time. For lower walls, the horizontal method is preferred; and the same
plan is adopted almost universally on espalier-rails. Hitt strongly recommends this
mode for most sorts of wall-trees; and for pears he adopts what is called the screw
stem, or training the stem in a serpentine manner, the branches going off horizontally as
in the ordinary straight stem. (Edin. Encyc. art. Hort.) Nicol agrees with most ex-
perienced gardeners, in preferring fan training to all other methods; and it may be ob-
erved, that this form comes nearer to that mode recommended by Knight, as affording
"evidence of a more regular distribution of the sap," than any other mode. It agrees
with the excellent general principles of pruning laid down by Quintiney, who first re-
duced this branch of gardening to scientific principles — and to the practice of the cele-
brated growers of peas at Montreuil, near Paris.

2586. Knight remarks, that when trees are, by any means, deprived of the motion which their branches
naturally receive from the winds, the forms in which they are trained operate more powerfully on their
permanent health and vigor than is generally imagined. "In this sentiment," says Nicol, "I perfectly
agree; and I may be allowed to add, that I have been engaged in the training of fruit-trees these twenty-
five years, and have trained them in a great variety of forms. Some in the Dutch style, running out two
branches first, perfectly horizontal, right and left, to the extent of three or four years each way, and
from these training shoots perfectly upright, at nine inches apart, to the top of the wall; some with
screwed stems and horizontal branches; some with upright stems and horizontal branches; some with
stems six feet high, with pendient, upright, and horizontal branches, so as to appear like a star; and others
in the serpentine manner; which last, I confess, I prefer to all other methods of training wall-trees. I have
altered many from the above forms to this both on walls and espaliers."

2587. Modes of training to check over vigorous growth are various; but all of
them depend on depressing the shoots either throughout their whole length or
operating on the young shoots only. When opportunity admits, or want of space on
one side of a wall requires, it is found conducive to moderation of growth and
the production of fruit to train the branches of trees over the wall and down
the other side. (fig. 431.) This is found to increase the prolificacy of vigorous
growing kinds, as the pear; and it also
succeeds well with the apple, cherry, and vine.

2588. Modes of training to encourage the growth of shoots proceed on the opposite prin-
ciple, and while over-luxuriant shoots are depressed, weak ones, which it is deemed proper
to encourage, are elevated and brought nearer to the perpendicular.

2589. Pruning and training, as applied to edgings and hedges, is performed by clipping
or cutting en masse, with the hedge-bill. (1328.) Hedges must be cut in autumn
when the wood is ripe: sometimes it is done in summer, which is admissible, as far as
respects the health of the plants, and consequent durability of the hedge when the lower
ends of the shoots are nearly ripe. If this is not the case, the operation is in-
jurious. The judicious gardener will weigh the circumstances of the case, and decide
accordingly.
Sect. VI. Watering, Stirring the Soil, Protecting, Supporting, and Shading.

2590. Eradication of weeds. The means of removal, are hoeing and weeding; and of destruction, exposing them, when hoed or pulled up, to the sun and air; or, what is in all cases better, taking them at once to the dunghill or compost-yard, to be destroyed by fermentation. These operations require to be performed almost every month in the year; but more especially in the beginning of summer, when the earth is teeming with vegetable life. Weeding in time, Marshall observes, is a material thing in culture, and the hand is generally more certain than the hoe.

2591. Stirring the ground among crops is nearly as essential as weeding, and is in some degree performed by the operation of hoeing. But the most effectual mode of stirring, and that now adopted by the best gardeners, is by the two-pronged fork or two-pronged hoe. (figs. 86. 97.) Every crop, whether planted in rows, or sown broadcast, ought to be subjected to this operation once or oftener in the course of its progress to maturity. Small crops, where the distances between the plants are not wide, ought to be stirred by a fork of two prongs, or even one prong. A narrow hoe is the usual instrument, but this always tends to harden the ground below, and form a sort of sole, which in many soils is impervious to air or rain. Besides, the operator is generally obliged to tread on and harden the ground stirred. "Breaking the surface," Marshall remarks, "keeps the soil in health; for when it lies in a hard or bound state, enriching showers run off, and the salubrious air and solar heat cannot enter. Ground," he adds, "should be frequently stirred and raked between crops, and about the borders, to give all a fresh appearance. There is a pleasantness to the eye in new-broken earth, which gives an air of culture, and is always agreeable." This last observation is particularly meant to apply in autumn, that the garden may not become dreary too soon, and so bring on winter before its time.

2592. Earthing up ought to go hand in hand with stirring in many cases; but rarely in the case of those plants which form their bulbs above the surface, as turnips and onions. This operation supports the stems of some crops, as the bean, cabbage, &c. and encourages the fertility or improves the quality of others, as the potatoe, leek, celery, &c. In winter also it protects them from the frost, and may then be applied to the turnip as no longer in a state of growth.

2593. Protecting, supporting, and shading. These operations are too little attended to, or attempted in a slovenly manner, by many gardeners. The grand subjects of protection are fruit-trees; and we have already (2206, &c.) given an enumeration of the various modes to which recourse is had. The simplest, and perhaps the best protection for general purposes, is that of throwing a net, either an old fishing-net or one formed on purpose of woollen yarn, over the whole tree, if a standard, or placing it against it, if trained to a wall, before it begins to blossom, and letting it remain there till the fruit is set. Marshall recommends this mode, justly observing, that after much expense and trouble to preserve blossoms from inclement weather, the business is often done to no purpose, or a bad one. Nicol’s opinion is not materially different. Single plants, as the raspberry, are to be supported by sticks or rods, and rows of climbers, by rods, spray, or branches, as peas, kidneybeans, &c.

2594. Shading is but little attended to, excepting in the case of transplantation; but it is of great importance in the fruiting season to certain plants which naturally grow in shady situations, as the strawberry and raspberry; and properly applied and accompanied with watering, tends to swell these fruits and others, as the gooseberry, and heads and roots of certain vegetables in hot weather, as the cauliflower, turnip, onion, radish; and the whole vegetable, as in the case of lettuce and other salads. The advantages of shading small fruits have been pointed out by Haynes (On the Culture of the Strawberry, Raspberry, and Gooseberry, 8vo. 1812.), and are very strikingly displayed in the gardening of the south of France and Italy.

Sect. VII. Watering.

2595. Watering, Marshall observes, "is a thing of some importance in cultivation, though not so much as many make it. It is a moot point, whether more harm than good, is not on the whole done by it. In a large garden it is a Herculean labor to water every thing, and so the temptation generally prevails, either wholly to neglect it, or to do it irregularly or defectively. To water nothing is too much on the dry side; but watering too much spoils the flavor, and renders esculents less wholesome." It may be observed, that the practice of the market-gardeners near London and Paris, and many private gardeners who practise in the southern counties, is somewhat at variance with the opinion of this experienced and very judicious author. The reason may probably be, that the region of his experience, Northamptonshire, is high and moist. He adds, however, that "strawberries and cauliflowers should generally be watered in a dry season; strawberries more particularly when in bloom, in order to set the fruit; and the
cauliflowers when they show fruit, in order to swell the head: in a light soil this ought unremittingly to be done. In very dry weather seedlings, asparagus, early turnips, carrots, radishes, and small salads, will need an evening watering.” He adds, “Water to the bottom and extent of the roots, as much as may be. The wetting only the surface of the ground is of little use, and of some certain harm, as it binds and cracks the earth, and so excludes the benefit of showers, dews, air, and sun, from entering the soil, and benefiting the roots as they otherwise would do. By wetting the surface of the ground, however, in a summer’s evening, as it makes a cool atmosphere, a dew is formed, which pervades the leaves, and helps to fill their exhausted vessels.” He recommends watering the roots of wall-trees in dry weather effectually; watering wall-trees with an engine in the evening refreshes them much, and helps to rid the trees and wall of insects and filth. Late in the summer, when the nights begin to get cold, it is time to leave off all watering, except things in pots and frames, which should have it then only in the morning. As watering is apt to make ground hidebound and unsightly, let the surface be occasionally stirred and raked, which will make future waterings enter the ground better: when the ground is hard on the top, the water runs away from its proper place, and half the labor is lost. Many things are impatient of being kept wet about the stalks, and therefore watering such plants should be generally at a little distance.”

2596. Watering over the leaves of wall-trees and espaliers is essentially necessary, because these trees by their position are deprived of a great degree of the natural showers which would fall on them, if their branches were freely diverged in the open garden.

Abercrombie, Forsyth, and Nicol strongly recommend watering the leaves of wall fruit-trees in dry weather every other day in the evening. Forsyth recommends watering infected trees with clear lime-water over the leaves, which he says soon destroys the red spider. Nicol uses water only; leaves oft' when the fruit approaches to maturity; and after it is gathered, recommences.

2597. Substitutes for watering can only be found in contrivances to lessen evaporation from the soil. Mulching is much used for this purpose in all the departments of the gardens of Italy and Spain. Even the Paris nurserymen cover the spaces between their lines of young trees with litter or leaves, as do the orange propagators at Nervi and the market-gardeners at Rome and Naples. In this country similar practices are sometimes tried. Maher, at Arundel Castle, during one very hot and dry summer, “sowed his seeds in drills, and covered the intervals between the drills with tiles, letting the edges of the tiles approach within an inch of the drills, and pressing them close into the earth. The tiles effectually preserved the roots from the scorching rays of the sun, and by preventing the evaporation of the moisture, under them, afforded support as well as protection.”

(Hort. Trans. vol. iv. p. 51.)

Sect. VIII. Vemnin, Insects, Diseases, and Accidents.

2598. Such vermin as moles, mice, and birds are to be caught by some of the traps or snares before described. (1473. to 1486.) After all the various devices that have been suggested and practised for keeping under the grub, caterpillar, and snail, the most certain is gathering them by hand at their first appearance every season. The grub, wire-worm, and maggot must be sought for by removing the earth from the roots of the plants where it is in action. The caterpillar gathered from the leaves beginning early in the season. The snail picked from the leaves or stalks of plants; or, in the case of new-sown crops, by strewing the ground with cabbage-leaves, or decaying leaves or haulm of any sort, (the process of decay inducing a degree of sweetness in the vegetable,) the snails will attach themselves to their under surface in the night, and may be picked off in the morning. Where the earth-worm is too abundant, they may be gathered in digging; or their casts removed, and the ground watered with clear lime-water. Ear-wigs, wood-lice, and similar insects, may be caught in hollow stalks of vegetables, or in the beetle-trap. Wasps are best destroyed by suffocating them in their nests; when this cannot be done, recourse must be had to bottles of horrid water, or other common modes. Watering is an effectual mode of destroying the red spider. Fumigation is generally resorted to in the case of the aphlis and thrips; but in the open garden, watering and rubbing, or brushing them off, will effect their destruction.

2599. Diseases in the vegetable kingdom are rather to be prevented than cured. A good soil on a dry sub-soil is the grand foundation of health, both in trees and herbaceous plants; and, on the supposition of proper culture, the judicious use of the knife to thin out superfluous, diseased, or injured branches, shoots, or leaves, and of the scraper, to remove mosses and rough bark already cracked and separating, are all that can be done to be depended on. Various unctions, oils, washes, compositions, and plasters, have been tried and recommended for curing the canker, mildew, blight, blotches, barrenness, gum, &c.; but few or none of them can be depended on. For the mildew, stewing with powdered sulphur is considered a specific; for the canker, &c., the most effectual mode of procedure is to correct the faults of the sub-soil and soil, renewing the latter entirely, if necessary; to cut out as far as practicable the diseased or wounded part; and in the case
of barrenness, to cut in or shorten even the healthy wood. Wherever amputation takes place, the wound will heal, if the air is excluded by prepared clay or any adhesive mixture, provided always, that the principle of life exists in tolerable vigor in the tree. Every thing, indeed, in plants as in animals, depends on the vis medicatrix nature.

Sect. IX. Gathering and Preserving Vegetables and Fruits, and sending them to a Distance.

2600. Gathering should commence as early and continue as late as possible with all kitchen-crops. At the same time, no vegetable ought to be gathered till it has attained the requisite degree of maturity, nor offered for use when it has begun to decay. What this degree is, often depends on the particular tastes of families, or their domesticities: thus cabbages are most esteemed in Edinburgh when fully headed and blanched; while, in London, they are preferred open and green, &c. Equal differences in taste as to peas, celery, lettuce, and indeed most other kitchen-crops, might be noticed. The operations of gathering kitchen-crops are either cutting off the part desired, breaking or pulling it off, as in the case of peas, beans, &c. or pulling or rooting up, as in the case of onions, turnips, potatoes, &c. Each of these operations ought to be performed with due regard to the plant, where that is to remain, as in the case of the pea; and to the adjoining plants of the same sort, as in the case of pulling turnips, onions, &c. As soon as any plant has furnished its crops or produce, the root and other remains ought to be immediately removed to the dung or compost heap. (See 1777.)

2601. Gathering fruits. This operation in the case of the small fruits, as the gooseberry, strawberry, &c. is generally performed by the under-gardeners; but wall and espalier fruit ought to be gathered by the head gardener. Where the utmost delicacy is desired, the berry-gatherer (fig. 149.) ought to be adopted for the small fruits, and also for plums, apples, and other fruits on espaliers. For the finer fruits, as the peach, nectarine, &c. the peach-gatherer (fig. 148.) lined with velvet, ought always to be adopted.

2602. Preserving esculents. The ice-house, as we have repeatedly observed, is found particularly useful for preserving esculent roots, and likewise celery during winter. Where parsnips and beet-roots are left in the ground over winter, Neill observes, "they must be lifted at the approach of spring, as they become tough and woody whenever there is a tendency to form a flower-stalk. These roots may, therefore, at this season, be placed in the ice-house, and preserved there for a considerable time in excellent order. In the summer season, during hot weather, various kinds of vegetables, as peas, kidneybeans, cucumbers, &c. can be kept fresh in it for several days; fruits gathered in the morning, which is the most proper time, may be here kept cool, and with all their freshness and flavor, until required for the dessert in the afternoon." (Supp. to Encyc. Brit. art. Hort.)

2603. Packing fruit and vegetables to be sent to a distance frequently forms a part of the gardener's duty. Fruits of the most delicate sorts, it is well known, are sent from Spain and Italy to England, packed in jars with sawdust from woods not resinous or otherwise ill tasted. One large bunch of grapes is suspended from a twig or pin laid across the mouth of the jar, so as it may not touch either the bottom or sides; sawdust or bran is then strewed in, and when full, the jar is well shaken to cause it to settle: more is then added, till it is quite full, when the supporting twig is taken away, and the earthen cover of the jar closely fitted and sealed, generally with fine stucco. In this way grapes may be sent from the most remote parts of Scotland or Ireland to the metropolis. When the distance is less, they may be sent enveloped in fine paper, and packed in moss. For extraordinary large bunches of grapes, the mode adopted by the Jewish spies (Numbers xiii.), and afterwards by Scechny, may be followed; that of carrying it suspended on a pole or staff resting on men's shoulders. The simplest mode for short distances is to wrap each bunch in fine soft paper, and lay them on a bed of moss in a broad flat basket with a proper cover.

2604. The more common fruits, cherries, and plums may be packed in thin layers, with paper and moss between each. Peaches, apricots, and the finer plums, may each be wrapped separately in vine or other leaves, or fine paper, and packed in abundance of cotton, flax, fine moss, or dried short grass. Moss, if it will be recollected, is apt to communicate its flavor to fine fruits, and so is short grass, if not thoroughly dried and sweetened. Cotton best preserves the bloom on peaches and plums.

2605. Common culinary vegetables are seldom sent to a great distance. The great art is to preserve them fresh, for which reason they ought to be laid loose in a close box, in the manner of botanic specimens; or closely packed in hampers; so as to exclude the air. The brassica and lettuce tribes, if pulled up by the roots, and as it were replanted in a box of sand with a wicker-work cover, may be sent a journey of two or three weeks without injury, as practised in Russia. Celery, turnips, &c. may be packed in sand; potatoes and other roots, loose. Legumes and other summer crops generally in moss.

Sect. X. Miscellaneous Operations of Culture and Management.

2606. The miscellaneous operations and duties of the gardener are numerous, and in the foregoing general view of kitchen-garden culture many particulars are necessarily omitted. Among these may be mentioned propagation of various kinds for the renewal of crops, mulching perennials, blanching leaves and stalks, rolling walks, preparing
composts, regrafting trees to introduce better sorts, or a variety of sorts on one tree, performing operations on their roots or stems to render them more fruitful, &c. These and other practices described in Part II. Book IV. of this work must be applied according to the judgment of the practitioner.

2607. A garden may be managed so as to produce good crops, and yet not so as to be agreeable to the eye. In general it may be observed, that the English gardeners excel in the former, and the Scotish in the latter part of practice. 'The Dutch and Flemish seem, in some degree to combine both, and this ought to be attempted, and persevered in till perfection is attained, by every British gardener.

2608. The first requisite to good management is a proper establishment of laborers, and resources, as to manure, seeds, repairs, &c. adequate to the extent and character of the garden. The next thing necessary is the entire independence of the gardener, as far as respects his province. The constant irksome interference of masters and mistresses, stewards, or others, is justly complained of by every gardener who understands his business. Where the proprietor is as it were head gardener, in that case he ought to make use of mere workmen, or of such gardeners as are not over-ambitious in their profession. In general it may be observed, that gardens so managed are ill managed, and often not well cultivated.

2609. The next requisite is a taste for order and neatness. This taste is generally acquired in youth from the instruction or imitation of parents or masters; but it may be greatly increased in grown-up persons, when they perceive its advantages, and in head gardeners, when a demand for it is created by their employers.

2610. Industry and steadiness are perhaps in no kind of life more necessary than in that of a gardener. Whole crops may be easily ruined by a day's neglect; and not only whole crops, as in the case of neglecting cucumber-frames, for example, but the whole produce of a year, or of several years, as in the case of neglecting a peach-house for one hot day.

2611. Unremitting attention and application. Unless a man is endowed with, and has well cultivated the faculty of attention, he can never excel in any thing. Without an ever-active attention, a gardener, will not see what is out of order, or unsightly in his garden, and of course will not think of correcting it. Many people are so deficient in this respect, that their knowledge is entirely confined to the few objects with which their mode of procuring living obliges them to be conversant. Something more than this is wanting in a gardener who would be master of his business; and it must be confessed, to the honor of many gardeners, that they excel in point of general observation and knowledge.

2612. The management of a garden, Marshall observes, consists in attention and application; the first should be of that wary and provident kind, as not only to do well in the present, but for the future; and the application should be of so diligent a nature, as "Never to defer that till to-morrow which may be done to-day, is of consequence in gardening; and neglect of times and seasons is fruitful of disappointment and complaint. It will often happen, indeed, that a gardener cannot do what he would; but if he does not do what he can, he will be most justly blamed, and perhaps censured, by none more than himself." (Introduct. to Gard. p. 59.)

Chap. V.

Of the general Management of Orchards.

2613. A private orchard is, sometimes, treated entirely as a kitchen-garden, in which case the foregoing chapter contains the general outline of management. Vegetables and small fruits, however, are seldom well flavored when grown under the shade and drip of trees, and, therefore, orchards are commonly either but slightly cropped, or laid down in pasture, after the trees are a few years established.

Sect. I. General Culture.

2614. Stirring the soil. "Many orchards would bear much better," Marshall observes, "if the ground were, before winter, dug over every second or third year, and dressed, by digging in some rotten dung, or sprinkling over the whole root and pigeons' dung, or that of any other poultry; this will wash in by rains and snows, and do much good. Or, if an orchard were ploughed, or rough dug, every year, immediately after the fall of the leaf, without manuring, it would be very beneficial."

2615. The taking of light, green crops near and among fruit-trees, according to Abercrombie, tends to keep the ground more effectually stirred and recruited, than if periodical diggings or hoeings were prescribed merely for the sake of the trees, because labor, for which the recompense is not direct, is constantly liable to be neglected. Nevertheless circumspection must be exercised, neither to dig too near, nor too deep among garden-trees, lest the roots should be loosened or injured. Digging the ground, Forsyth observes, provided it be not done so deep as to hurt the roots, by admitting the sun and rain to meliorate the ground, will keep the trees in a healthy flourishing state. When the surface of the ground is wet, and has a little descent, it may be formed into a kind of ridges, by making a furrow, from one to two feet deep, between every two rows, sloping the ground regularly on each side, from a reasonable distance to the bottom of the furrow. These hollows will carry off the water, and render the surface dry and healthy. If pasture, the turf may be first pared off; and afterwards relaid when the furrow is made. (Forsyth on Fr. Trees, p. 305.)

Nicoll directs the whole ground of an orchard to be dug in the autumn, and laid up in a rough state for the winter, giving it as much surface as possible, in order that the weather may fully act upon and meliorate the soil; thus following it as far as the case will admit. Observe to dig carefully near to the trees, and so as not to hurt their roots and fibres. If the soil be shallow, and if these lie near the surface, it would be advisable to dig with a fork instead of the spade. (Kal. p. 262.)
2616. Manuring. The natural defects of the soil, the habits of fruit-trees, and the preference of a species for a particular soil or manure, are to be considered. The hotter dung are not likely by fruit-trees; and those of the horse and the sheep, if not wanted where they would be beneficial alone, should be mixed with twice as much of the cooler dungs, and three times as much fresh earth or road-drift; or with twice the bulk of earthy matter, if the cooler dungs are not to be obtained. The residue of neats' dung, properly reduced by keeping, is a good simple manure for most fruit-trees, and excellent in a compost; but where the soil is naturally cold, a little ashes of coals, wood, straw, or burnt turf, or a minute proportion of soot, ought to be incorporated with it. Hog-dung is accounted to have a peculiar virtue in invigorating weak trees. Rotted turf; or any vegetable refuse, is a general manure, excellent for all soils not already too rich. One of the best correctives of too rich a soil is drift sand. For an exhausted soil, where a fruit-tree that has been an old profitable occupant is wished to be continued, a dressing of animal matter is a powerful restorative; such as hog's or bullock's blood, offal from the slaughter-house, refuse of skins and leather, decomposed carrion: also urine diluted with water. The drainings of dung laid on as mulch are highly serviceable. In a soil which does not effervesce with acids, a little lime, dug in a spit deep, is beneficial to fruit-trees. (Abercrombie.)

Forysth says, "Orchards ought to be dugged once in two or three years." Marshall allows of some rotten dung being dug in, or of sprinkling the whole over with soot and pigeon's dung; he adds, "It is not advisable to give trees much dung; a little lime, only surface-dug, is good."

2617. Cropping. Marshall, Abercrombie, and Forysth allow of moderate cropping among standard fruit-trees; but the following observations of Nicol are the most definite on the subject:—

It is proper to crop the ground among new-planted orchard-trees for a few years, in order to delay the expense of hoeing and cultivating it; which should be done until the temporary plants are removed, and the whole be sown down in grass. But it is by no means advisable to carry the system of cropping with vegetables to such an excess as is frequently done. If the bare expense of cultivating the ground, and the crop, be paid by such cropping, it should be considered enough. As the trees begin to produce fruit, begin also to relinquish cropping. When by their productions they defray all expenses, crop no longer. I consider these as being wholesome rules, both for the trees and their owners.

Rules.—1. Crop to within two feet of the trees the first year; a yard the second; four feet the third; and so on until finally relinquished; which of course would be against the eighth year, provided the trees were planted at thirty or forty feet apart with early bearing sorts between. By this time, if the kinds have been well chosen, the temporary trees will be in full bearing, and will forthwith defray every necessary expense while they remain, or until the principal trees come into a bearing state, and it become necessary to remove them; after which, the ground should be sown down in grass. But until then, the ground should be properly cultivated, though not cropped close to the trees; and a moderate quantity of manure should be dug in every second or third season." (Kal. 582.)

Sect. II. Pruning Orchard-trees.

2618. In pruning a newly planted orchard or standard tree, the first object is the formation of a head. According to Abercrombie, this ought in most kinds to be "circular, compact, and proportioned to the strength of the stem, with the branches well distributed, and sufficiently open in the centre to admit the free circulation of air." In the first spring "after a young standard has been planted, examine the primary branches, to see whether they will be sufficient, with the secondary laterals to be forced out by shortening, to form a good head." The minor branches should be so placed as to balance each other, and be equally distributed round the tree. Thus, three in a triangle; four at right angles; five, six, and even seven, shooting at pretty equal distances, might be retained: but it is seldom that more than four well placed offer, which is a good number. These first branches, if there be no secondary laterals, or none well placed, should be shortened down to two or four eyes each; or reduce a strong shoot to one third of its length, and a weak shoot to two thirds. The second spring, again revise the branches and secondary shoots, and reserve only so many as are vigorous and well distributed. Afterwards leave the head to form of itself, cutting out superfluous and ill placed shoots, and shortening for the production of new laterals only to fill a vacancy. Luxuriant limbs, which are likely to be disproportionately large, should be rejected as weakly shoots. In the third or fourth year after planting a maiden tree, the foundation of a good head having been obtained by judicious shortening, and the plant sufficiently strengthened, it will become proper to let the new growths look as much as they will, which, when you have obtained a head, nothing is more to be desired. To this end, the lower branches should not be shortened at all, and the upright leaders very little. But where two shoots cross, let the worst be cut out. Moderate-sized and slender shoots are more fruitful than strong luxuriant wood."

2619. The object of pruning young standard-trees, Nicol observes, "is to form a proper head. Generally speaking, the shoots may be pruned in proportion to their lengths, cutting clean away as close one another, and fanning the tree out towards the extremities on all sides; thereby keeping it equally poised, and fit to resist the effects of high winds. When it is wished to throw a young tree into a bearing state, which should not be thought of, however, sooner than the third or fourth year after planting, the leading branches should be very little shortened, and the lower or side branches not at all; nor should the knife be used, unless to cut out such shoots as cross one another, as above hinted."

2620. Pruning bearing trees. "After an orchard-tree is come into bearing," Abercrombie observes, "continue at the time of winter pruning, either every year, or every two, three, or four years, as an occasion is perceived, to cut out unproductive..."
wood, crowded spray, and decayed parts. Also reduce long and outrunning ramblers, and low stragglers, cutting them to some good lateral that grows within limits. Where fruit-spurs are too numerous, then cut the strongest and most unsightly. Also keep the tree pretty open in the middle. If it be necessary to take off large branches from aged trees, use a chisel or saw, and afterwards smooth the wound with a paring-knife. In case old wood is to be cut down to young shoots sprouting below, to make the separation in summer will be of more advantage to those young shoots, though it is not a common practice, on account of the liability of many stone-fruit bearers to exude gum, when a large branch is lopped in the growing season. Observe to keep the stem clear from all lateral shoots, and eradicate all suckers from the root.

2621. In pruning aged trees, that have run into a confusion of shoots and branches, and whose spurs have become clustered and crowded, the saw and the knife may be exercised with freedom; observing to cut clean away all useless spray, rotten stumps, and the like excrescences. Thin out the spurs to a moderate consistency, so as to let the air circulate freely among the leaves and fruit in the summer season, and to admit the rays of the sun, so as to give the fruit color and flavor.

Marshall strongly recommends "thinning the branches of orchard-trees for the same objects," adding, "that it is in general much neglected." He recommends "a little pruning of standards every year; and a general one (rather free) every three or four years, to cut out what is decayed, and some of the older wood, where a successional supply of young may be obtained to succeed, as the best way to keep the trees in vigor, and have the best of fruit; for that which grows on old wood gets small and austerer." The same author judiciously remarks, that trees with heavy fruit, as the apple and pear, should have, if possible, their branches rather upright; but that light-fruited trees, such as the cherry, will admit of drooping branches.

2622. The season for pruning orchards is generally winter or early in spring—not later than February, according to Abercrombie and Nicol. Quintiney says, "A weak tree ought to be pruned directly at the fall of the leaf." And Abercrombie, "To prune in autumn strengthens a plant, and will bring the blossom-buds more forward; to cut the wood late in spring tends to check a plant, and is one of the remedies for excessive luxuriance."

2623. Treatment of deformed or diseased trees. Where a tree is stunted, or the head ill shaped, from being originally badly pruned, or barren from having overborne itself, or from constitutional weakness, the most expeditious remedy is to head down the plant within three, four, or five eyes (or inches, if an old tree) of the top of the stem, in order to furnish it with a new head. The recovery of a languishing tree, if not found, will be further promoted by taking it up at the same time, and pruning the roots; for, on the one hand, the depriving too luxuriant a tree of part even of its sound healthy roots will moderate its vigor; so, on the other, to relieve a stunted or sickly tree of cankered or decayed roots, to prune the extremities of sound roots, and especially to shorten the dangling tap-roots of a plant, affected by a bad sub-soil, is in connection with heading down or very short pruning, and the renovation of the soil, and draining, if necessary, of the sub-soil, the most availling remedy that can be tried. (Abercrombie.)

2624. A tree often becomes stunted from an accumulation of moss, which affects the functions of the bark, and renders the tree unfruitful. This evil is to be removed by scraping the stem and branches of old trees with the scraper; and on young trees a hard brush will effect the purpose. Abercrombie and Nicol agree in recommending the finishing of this operation by washing with soap-suds, or a medicated wash of some of the different sorts for destroying the eggs of insects. In our opinion lime-water, or even water alone, is better than any of these applications.

2625. Wherever the bark is decayed or cracked, Abercrombie and Forsyth direct its removal. Lyon, of Edinburgh, has lately carried this practice to so great a length as even to recommend the removal of a part of the bark on young trees. Practical men, in general, however, confine the operation to the cracked bark which nature seems to attempt throwing off; and the effect, in rendering the trees more fruitful and luxuriant, is acknowledged by Neil in his Account of Scottish Gardening and Orchards, and by different writers in the London and Edinburgh Horticultural Transactions.

2626. The other diseases to which orchard-trees are subject, are chiefly the canker, gum, mildew, and blight, which, as we have already observed, are rather to be prevented by such culture as will induce a healthy state, than to be remedied by topical applications. Too much lime, Sir H. Davy thinks, may bring on the canker, and if so, the replacing a part of such soil with alluvial or vegetable earth, would be of service. The gum, it is said, may be constitutional, arising from offensive matter in the soil; or local, arising from external injury. In the former case, improve the soil; in the latter, apply the knife. The mildew, it is observed by Knight and by Abercrombie, "may be easily subdued at its first appearance, by scattering flour of sulphur upon the infected parts." As this disease is now generally considered the growth of parasitical fungi, the above remedy is likely to succeed. For the blight and caterpillars, Forsyth recommends burning of rotten wood, weeds, potato haulm, wet straw, &c. on the windward side of the trees when they are in blossom. He also recommends washing the stems and branches of all orchard-trees with a mixture of "fresh cow-dung with urine and soap-suds, as a white-washer would wash the ceiling or walls of a room." The promised advantages are, destruction of insects, and "fine bark;" he adds, "when you see it necessary take all the outer bark off."
GATHERING and storing orchard-fruit.

2627. The gathering of orchard-fruits, and especially apples, from standards, should be performed in such a manner as not to damage the branches, or break off the spurs. Too frequently the fruit is allowed to drop, or they are beat and bruised by shaking the tree, and using long poles, &c. Nicol directs that "they should never be allowed to drop of themselves, nor should they be shaken down, but should be pulled by the hand or apple-gatherer. (1347.) This may be thought too troublesome a method; but every body knows that bruised fruit will not keep, nor will it bring a full price. The expense of gathering, therefore, may be more than defrayed, if carefully done, by saving the fruit from blemish." (Kal. 257.)

Forsyth says, "As apples shaken or beaten down with a pole never keep in winter, they ought all to be hand-picked by a person standing on steps made on purpose. The step-ladder should be light, in two pieces, to disengage the back at pleasure, by drawing the bolt; and they should have a broad step at top for a man to stand on, and to place a basket by his feet. In the larger baskets or hampers, in which the fruit is to be placed to be wheeled away, lay some short grass mowings, perfectly dry (which ought to be provided in summer, and kept dry), to prevent the fruit from being bruised."

2628. In respect to the time of gathering, Nicol recommends "that pears and apples should not be pulled till their seeds be of a dark brown, or blackish color." The criterion of ripeness, adopted by Forsyth, is their beginning to fall from the tree. He says, "Observe attentively when the apples and pears are ripe; and do not pick them always at the same regular time of the year, as is the practice with many. A dry season will forward the ripening of fruit, and a wet one retard it; so that there will sometimes be a month or five weeks difference in the proper time of gathering. The method that I have practised is, to observe when the fruit begins to fall (I do not mean what we call windfalls, or the falling of such as are infested with the caterpillar, &c., but sound fruit); I then put my hand under it; and if it comes off without any force being used, I take it for granted that the fruit is perfectly ripe; unless the tree be sickly, which is easily known by the leaves or fruit being shrivelled. If the foregoing observations are attended to, the fruit will keep well, and be plump; and not shrivelled, as is the case with all fruit that is gathered before it is ripe."

Marshall says, "Gather pears of the summer sorts, rather before they are ripe, as when thoroughly so they eat mealy, if kept above a day or two; even when gathered as they ought to be, in a week or less they will begin to go at the core. They should not, however, be gathered while they require much force to pull them off. Autumn pears must also not be full ripe at the time of gathering, though they must keep longer than those of the summer. Winter pears, on the contrary, should hang as long on the trees as they may, so as to escape frost, which would make them flat in flavor, and not keep well. Generally they may hang to the middle of October on full standards, a week longer on dwarfs, and to the end of the month on walls; but yet not after they are ripe. The art of gathering is to give them a lift, so as to press away the stalk, and if ripe they readily part from the tree. Those that will not come off easy, should hang a little longer; for when they come hardly off, they will not be so fit to store, and the violence done at the footstalk may injure the bud there formed for the next year's fruit. Let pears be quite dry when pulled, and in handling avoid bruising the fruit, or in any way bruising it, as those which are hurt not only decay themselves, but presently spread infection to those near them: when suspected to be bruised, let them be carefully kept from others, and used first: as gathered lay them gently in shallow baskets." — "The jargonelle pear," Forsyth observes, "keeps best on the tree, as if gathered, it rots almost immediately."

2629. With regard to keeping of orchard-fruits, the old practice, and that recommended by Marshall and Forsyth, commences with sweating. Nicol, and most modern gardeners, omit this process, and spread the fruit thinly on shelves, or the floor of the fruit-room. As to the keeping of apples, Marshall observes, "those which continue long for use should be suffered to hang late, even to November, if the frost will permit, for they must be well ripened, or they will shrink. Lay them in heaps till they have sweated a few days, when they must be wiped dry. Let them then lie singly, or at least thinly, for about a fortnight, and be again wiped, and immediately packed in boxes and tampers, lined with double or treble sheets of paper. Place them gently in, and cover them close, so as to keep air out as much as possible. Preserve them from frost through the winter. Never use hay for the purpose. Some of the choicest table sorts of apples may be treated as directed for the best pears."

2630. Sweetening and storing winter pears. Winter pears, according to Marshall, "should be laid in a dry airy room, at first thinly for a few days, and then put them in heaps to sweat; in order to which, a blanket thrown over them will help. The fermentation must be watched, and when it seems to have passed the height of sweating, wipe the fruit quite dry gently with fine flannel, or clean soft linen, and store them carefully. The storing is thus: those to be used first, lay by singly on shelves, or on the floor, i.e., a dry southern room, on clean dry moss, or sweet dry straw, so as not to touch one another. Some, or all the rest, having first lain a fortnight singly, and then nicely culled, are to be spread on shelves, or on a dry floor. But the most superior way is, to pack in large earthen, or China or stone jars, with very dry long moss at the bottom, sides, and also between them, if it might be. Press a good coat of moss on the top, and then stop the mouth close with cork, or otherwise, which should be rosined round with about a
twentieth part of bees' wax in it. As the object is effectually to keep out air (the cause of putrefaction), the jars, if earthen, may be set on dry sand, which put also between, round, and over them, to a foot thick on the top. In all close storing, observe, there should be no doubt of the soundness of the fruit. Guard, in time, from frost those that lie open. Jars of fruit must be soon used after unsealing.”

2631. Sweating and storing apples and pears as practised by Forsyth. “When the fruit is carried to the fruit-room, lay some of the dry short grass on the floor, in the area of the room; then take the fruit gently out of the baskets, and lay it in heaps on the top of the grass, keeping each sort in a separate heap; the heaps may be from two to three feet high, or according to the quantity of fruit that you have. When the heaps are completed, cover the tops at least two inches thick with short grass, in order to sweat them. Let them lie a fortnight, then open the heaps and turn them over, wiping each apple or pear with a dry woollen cloth, which should be frequently dried during the process, observing now to lay in the middle the fruit which before was at the top. Let the heaps now remain eight or ten days, covered as before; by that time, they will have thrown out the watery crudities which they may have imbibed during a wet season; then uncover the heaps, and wipe the fruit carefully one by one, as before, picking out every one that is injured, or has the least spot, as unfit for keeping. During the time that the fruit is sweating, the windows should be left open, except in wet and foggy weather, to admit the air to carry off the moisture which perspires from the fruit. The perspiration will sometimes be so great, that, on putting your hand into the heap, it will come out as wet as if it had been dipped into a pail of water; when in this state it will be necessary to turn and wipe the fruit.”

2632. In preserving fruit, the common practice has been, to lay it on clean wheat-straw; but I find, by experience, that, when any of the fruit begins to decay, if it be not immediately picked out, the straw, by imbibing the moisture from the decayed fruit, will become tainted, and communicate a disagreeable taste to the sound fruit. “The fruit on shelves,” he adds, “should be turned two or three times during the winter; as delicate and tender fruit, by lying long without turning, is apt to rot on the underside, even if perfectly sound when laid up. Be particularly careful, however, to pick out all the damaged fruit. When the fruit is laid in, put the earliest sorts on the lower shelves, or in the lower drawers, according to their time of coming in, beginning with the noshuch, golden rennet, and jenneting apples, and bergamot and over pears; thus, by proper management, you may have a constant succession of fruit from one season to the other. Those who keep their fruit in storerooms, for the supply of the London and other markets, as well as those who have not proper fruit-rooms, may keep their apples and pears in baskets or hampers; putting some soft paper in the bottoms and round the edges of the baskets, &c., to keep the fruit from being bruised; then put in a layer of fruit, and over that another layer of paper; and so on, a layer of fruit and of paper alternately, till the basket or hamper be full: cover the top with paper three or four times double, to exclude the air and frost as much as possible. Every different sort of fruit should be packed separately; and it will be proper to fix a label to each basket or hamper, with the name of the fruit that it contains, and the time of its being fit for use.”

2633. But the best way of keeping fruit, is to pack it in glazed earthen jars. “The pears or apples must be separately wrapped up in soft paper; then put a little well-dried bran in the bottom of the jar, and over the bran a layer of fruit; then a little more bran to fill up the interstices between the fruit, and to cover it; and so on, a layer of fruit and bran alternately, till the jar be full; then shake it gently, which will make the fruit and bran sink a little; fill up the vacancy at top with more bran, and lay some paper over it, covering the top with a piece of bladder to exclude the air; then put on the top or cover of the jar, observing that it fits as closely as possible. These jars should be kept in a room where you can have a fire in wet or damp weather.”

2634. Nicol’s opinion as to the sweating of fruits is thus given: “I consider it an error to sweat apples, as it is termed, previous to storing them, either in the common way, with straw or hay, or as recommended by Forsyth, by the use of short grass. The fruit ever after retains a bad flavor. It should never be laid in heaps at all; but if quite dry when gathered, should be immediately carried to the fruit-room, and be laid, if not singly, at least thin on the shelves; the room being properly fitted up with shallow shelves on purpose, being well aired, and having a stove in it, that damp may be dried off when necessary.” He adds, “If the finer fruits are placed on any thing else than a clean shelf, it should be on fine paper. Brown paper gives them a flavor of pitch. The finer large kinds of pears should not be allowed even to touch one another, but should be laid quite single and distinct. Apples, and all pears, should be laid thin; never tier above tier. Free air should be admitted to the fruit-room always in good weather, for several hours every day; and in damp weather a fire should be kept in. Be careful at all times to exclude the frost from the fruit, and occasionally to turn it when very mellow.”

2635. Gathering and storing nuts. Walnuts are generally beat off the trees with poles; but it does not appear that any harm would result to the fruit from leaving them to drop, or be shaken off by winds, or in part shaking them off. Sweating may be applicable to them, in order to the more ready separation of the outer or soft skin from the hard shell. This effected, they are to be spread thin till quite dry, when they may be preserved in bins, or boxes, or heaps.

2636. Walnuts for keeping, Forsyth observes, “should be suffered to drop of themselves, and afterwards laid in an open airy place till they are thoroughly dried; then pack them in jars, boxes or casks, with fine clean sand, that has been well dried in the sun, in an oven, or before the fire, in layers of sand and walnuts alternately; set them in a dry place, but not where it is too hot. In this manner, I have kept
PACKING and providing each packing matters, the whole of the fruit, and put them in a cold place, where they will become in due course

2637. The chestnut is to be treated like the walnut, after the husk is removed, which, in the chestnut, opens of itself. Knight (Hor. Tr. i. p. 247.) preserves chestnuts and walnuts during the whole winter, by covering them with earth as cottagers do potatoes.

2638. Alberts may always be gathered by hand, and should afterwards be treated as recommended for walnuts. Forsyth recommends packing nuts, intended for keeping, in jars or boxes of dry sand.

2639. Other fruits. The barberry and cornel, or dog-wood berry, are used immediately, when gathered, as preserves. The medlar is not good till rotten ripe. It is generally gathered in the beginning of November, and placed between two layers of straw, to forward its maturation. “Others,” Marshall observes, “put medlars in a box on a three-inch layer of fresh bran, moistened well with soft warm water; then strew a layer of straw between them, and cover with fruit two inches thick; which moisten also, but not so wet as before.” In a week or ten days after this operation, they will be fit for use. Quinces are gathered in November, when they are generally ripe. After sweating in a heap for a few days, they are to be wiped dry, and placed on the fruit-shelf at some distance from each other. The service, or sorb apple, never ripens on the tree in England. Where grown, it is gathered late in autumn, in a very austere state, and laid on wheat-straw to decay. It thus becomes eatable in a month.

SECT. IV. Of packing Orchard and other Fruits for Carriage.

2640. In packing fruit to be sent to a considerable distance, great care is requisite. It should not, Forsyth observes, be packed in baskets, as they are liable to be bruised among heavy luggage, and the fruit, of course, will be injured. I would, therefore, recommend boxes made of strong deal, of different sizes, according to the quantity of fruit to be packed. The following are the dimensions of the boxes in which we send fruit by the coach to Windsor and Weymouth, for the use of his Majesty and the Royal Family; viz.: The larger box is two feet long, fourteen inches broad, and the same in depth. The smaller box is one foot nine inches long, one foot broad, and the same depth. These boxes are made of inch-deal, and well secured with three iron clamps at each corner: they have two small iron handles, one at each end, by which they are fastened to the roof of the coach; in these boxes we send melons, currants, pears, peaches, nectarines, plums and grapes, packed so as always to have the heaviest fruit at bottom. The melons are wrapped up in soft paper: the pears, peaches, nectarines, plums, and grapes are first wrapped up in vine-leaves, and then in paper. The cherries and currants are packed in a flat tin box, one foot four inches long, ten inches broad, and four deep.

2641. In packing, proceed thus:—First, put a layer of fine long dry moss in the bottom of the tin box, then a layer of currants or cherries, then another layer of moss, and so on, alternately, fruit and moss, until the box is so full, that, if the lid is hinged up, the fruit may be so firmly packed as to preserve them from friction. Make a layer of fine moss and short, soft, dry grass, well mixed, in the bottom of the deal box; this with moss, and then plump and fine, and cause them packed tight in between all the rows, and also between the melons in the same row, till you have finished the layer; choosing the fruit as nearly of size as possible, filling up every interstice with the moss and grass. When the melons are packed, lay a thin layer of moss and grass over them, upon which place the tin box with the currants, packing it firmly all round with moss, and then put a thin layer of moss over the box, and pack the pears firmly (but so as not to bruise them) on that layer, in the same manner as the melons; and so on with the peaches, nectarines, plums, and lastly, the grapes, filling up the box with moss, that the lid may shut down so tight as to prevent any friction among the fruit. The boxes should have locks, and two keys, which may serve for them all; each of the persons who pack and unpack the fruit having a key. The moss and grass should always be returned in the boxes, which, with a little addition, will serve the whole season, being shaken up and well aired after each journey, and keeping it sweet and clean. After the wooden box is locked, it will be necessary to cord it firmly. My reason for being so particular on packing of fruit is, that I have known instances of its being totally spoiled in the carriage from improper packing. By pursuing the above method, we have never failed of success, and if fruit be packed according to the foregoing directions, it may be sent to the farthest parts of the kingdom, by coaches or waggons, with perfect safety.

2642. Miscellaneous points of orchard culture. As in treating of kitchen-garden culture, so here various lessor points of culture and management are omitted, which the judicious gardener will not overlook in practice; provided he has, or ought to have, the whole art and science of gardening, as it were, stored up in his mind, and ready to apply on every occasion. Among these points may be named the occasional grafting of orchard-trees, with a view either to introduce new or preferable sorts, or to fill up the head of a tree. Thinning out temporary trees; introducing young trees in intervals of old orchards to succeed the old; guarding from thieves; and a variety of other matters, which circumstances will always suggest to the observing eye and fertile mind of a gardener attached to his profession. Among these things, one of the first consequence is attention to order and neatness.

2643. In regard to neatness and order, see 2355. to 2373.; and with respect to recent improvements, which have not been fully sanctioned by extensive adoption, they have been already enumerated in Part II. Book IV. On the Operations of Gardening.

CHAP. VI.
Construction of the Culinary Forcing Structures and Hot-houses.

2644. The general principles of design in forcing and hot-house structures have been already laid down (1591 to 1692); and, therefore, the object, in this chapter, is to detail the most approved practice in regard to the particular construction of such as belong to the culinary and fruit gardens. These are the pinery, viney, peach-house, cherry-house, fig-house, culinary pits, frames, and mushroom-house.

Sect. I. Of the Construction of the Pinery.

2645. The external form of a pinery varies less than that of any other description of hot-house. The necessity, in glass structures, of placing all plants intended to thrive near the glass, and a bed of bark or leaves for plunging pots, being most convenient, when flat or gently sloping, have led, in almost all cases, to a low and rather flat roof, nearly parallel to the bark-bed. This gave rise, many years ago, to the growing of pine in pits, as practised by the Dutch, and generally on the continent, and as recently adopted in this country by most commercial gardeners; by Nicol, in giving designs for this class of buildings; and by Baldwin, one of the best pine-growers of the present day.

2646. The pinery of Nicol consists of three pits in a range; one for crowns and suckers, one for succession, and one for fruiting plants. The fruiting-pit to be placed in the centre, and the other two, right and left; forming a range of a hundred feet in length; which would give pine-apples enough for a large family. The fruiting-pit to be forty feet long, and ten feet wide, over walls; and each of the others to be thirty feet long, and nine feet wide, also over walls. The breast-wall of the whole to be on a line, and to be eighteen inches above ground. The back wall of the centre one to be five feet, and of the others, to be four and a half feet higher than the front. The front and end flues to be separated from the bark-bed by a three inch cavity, and the back flues to be raised above its level.

2647. The furnaces may either be placed in front, or at the back, according to conveniency; but the strength of the heat should be first exhausted in front, and should return in the back flues. The fruiting-pit would require two small furnaces, in order to diffuse the heat generally, and keep up a proper temperature in winter; one to be placed at each hand; and either to play, first in front, and return in the back; but the flues to be above, and not alongside of one another; as in the latter way they would take up too much room. The under one to be considered merely as an auxiliary flue, as it would only been wanted occasionally. None of these flues need be more than five or six inches wide, and nine or ten deep. Nor need the furnaces be so large, by a third or fourth part, as those for large forcing-houses; because there should be proper oil-cloth covers for the whole, as guards against severe weather, which would be a great saving of fuel. The depth of the pits should be regulated so as that the average depth of the bark-beds may be a yard below the level of the front flues; as to that level the bark will generally settle, although made as high as their surfaces, when new stirred up. If leaves, or a mixture of leaves with dung, are to be used instead of bark, the pits will require to be a foot, or half a yard deeper.

2648. Large pineries should be turned to other purposes, and such erected as are described above. There cannot be a doubt respecting the satisfaction that would follow, if to have good fruit at an easy rate were the object. I have given designs for no other kinds of new pineries these six years past, but such as these; with some variations respecting extent, however, in order to suit different purses.

2649. The pinery of Baldwin consists of two structures, the succession-bed and fruiting-house.

2650. The succession-beds or frame (fig. 432), in which the young plants are to remain both winter and summer, should be constructed of timber, seven feet wide, and seven feet three inches high at the back, the front being in the same proportion. The method of preparing the bed is as follows:—"Sink your
pit (2) three feet three inches deep, as long as you require, and sufficiently broad to admit of linings on each side (1, 3); make a good drain at the bottom of the pit to keep it dry; then set posts, about the dimensions of six inches square, in the pit, at convenient distances (say about the width of the top lights), and case it round with one inch and a half deal wrought boards above the surface, and below with any inferior boards or planks. The dimensions of my succession-beds or frame are thirty-nine feet long, and seven feet wide; containing two hundred and seventy-three square feet, which will hold three hundred and fifty suckers, from the end of September till the seventh of April." (Cult. of Anan. p. 11.)

2651. The fruiting-house (fig. 433.) is a pit with a walk behind; "in it the glass should be closely puttied, to keep out the cold air, and to retain the warm, and in the back there should be three lids (b), to admit air; the dimensions of each to be three feet long and one foot deep. The flue makes only one course in the passage behind." (Cult. of Anan. p. 19.)

2652. Aiton's pine-pits at Kensington (fig. 434.) are constructed exactly in Baldwin's manner, with this difference, that the sub-soil at Kensington being moist, they are raised on a small platform (a, b) above the surface, instead of being sunk under it, as Baldwin's are. They have, also, the addition of a gutter in front (c), which, though at first sight it may appear trifling, yet, in practice, is of very material consequence, by keeping the lining dry, and not chilling the heat in the very part where it should penetrate to the interior of the pit. Occasionally some plants are fruited in these pits, especially at Kew, but in general they are removed to a low house (fig. 435.) of a most economical and judicious construction, and calculated both for the growth of pines and vines. This house is fifteen feet wide within walls; the pit (a) is nine feet wide; the back path (b) forms a border for the roots of the vines; the pit is surrounded by a flue (c, d); the curb is two feet three inches from the glass in front (e), and four feet eight inches from it behind (f); the vines are planted in the back border (b), and trained under the roof directly over it and over the back flue; and others are planted in the front border (g); and trained up the rafters. The length of the houses in the royal gardens at Kensington varies from thirty-three to fifty feet (fig. 436.):

Each house has two furnaces, one for constant use, and another for giving an extra supply of heat in very severe weather. The first (a) proceeds directly to the front corner (b), thence along the front to the opposite end (c), then along the back of the pit (d, e), passing under the back path, or border, and terminating in a chimney (f) beside the furnace. The other furnace is placed at the opposite end of the house (g); has a short flue under the back path, which conducts it to the back course of the principal flue (at d), which it
joins, and the smoke of the two fires moves in the same tunnel (from \(d\) to \(e\)), and passes out by the same chimney. When this second furnace is not in use, its connection with the flue of the first is cut off by a damper at the point of junction \(d\). A very small fire made in this furnace, in severe weather, not only adds to the heat of the house by its own power, but by increasing the draught, or rate of burning, of the fire in the other furnace. In addition to the fire heat, a steam-apparatus has been lately erected, and the tubes conducted round the houses on the tops of the flues (fig. 436. \(d, e\)); this is found to give a great command of heat; and also to admit of filling the house with vapor at pleasure. The height of the house from the ground to the top of the back wall, is only nine feet (fig. 437.); the rafters of the roof are placed about four feet apart, centre from centre;

or about twenty-four sashes are given to every hundred feet; the front sashes \((a)\) are only eighteen inches high, and slide past each other; the middle end sash \((b)\) also slides; the sill of the door \((c)\) and the back path, or border, are on a level with the outer surface of the ground, to admit the easy wheeling in of tan, &c.; the front border \((d)\) is raised considerably above it, on account of the wet bottom; the back sheds are low and neat; and the furnaces sunk three feet below the surface (fig. 436. \(h, h\)) to give them a better draught; and this also serves to drain the back border. The houses are placed in pairs, the furnaces for general use at the extreme ends of the range, and the auxiliary ones in the middle, where the steam-boiler is also placed, but worked by a fire apart; on the whole, no plan of pine-stove that has yet appeared is more simple, neat, economical, and complete than this; the only objection we have to them, is, that owing to the great thickness of wood employed in the bars of the sashes, they are rather dark and gloomy within; but this might easily be remedied by the substitution of light iron rafters, with wooden-framed sashes sliding in them, but the bars of the sashes formed of iron. It is true, gloomy as these houses are, the pines thrive in them as well as can be wished; but probably by having more light, they might thrive so as to surpass all expectation.

2653. The pinery of Knight may be described as a pit forty-five feet long, nine feet nine inches wide, the front parapet eighteen inches, and the back wall nine feet high. The roof is constructed of iron sash-bar, fixed, and the bars curved, so that the versed sine of the segment is about twelve inches. Air is given by horizontal openings immediately under the copings of both walls. More light is admitted into such a pit in March, than into a common flat-roofed pit with wooden sashes in May or June.

2654. As an example of a pinery and grapery combined, we refer to a curvilinear structure (fig. 438.), erected from our designs, at Langport in Somersetshire. This house...
is fifty feet long by sixteen feet wide, contains 370 superficial feet of bark-pit for pine-plants; 1400 superficial feet for training vines; and space for 500 pots of strawberries or French beans; quantities greater in proportion to the glass roof, than have hitherto been obtained in any hot-house of the common form and similar dimensions. This structure is entered by lobbies at each end (fig. 439. 1), which communicate with a back passage, having a glass roof and trellis for vines (2): in the back wall of this passage, and also in the front of the house, are glazed ventilators opening outwards (fig. 440. 3), through which the vines (5) are introduced and withdrawn at pleasure. The pine-pits (7) are raised so as to be as near the glass as is desirable, by vaulting them beneath (6); against the front of these pits, shoots of vines are brought down from the roof, and trained (9), and pots are placed over the front flue (8). The vines, close under the roof, are trained on moveable trellis-rods, composed of a centre and two side wires, and placed five feet apart; these rods are hinged to the front props, and supported in the middle of the roof, and at top, by chains and hooks, and in this way can be raised or lowered at pleasure. This house, since its erection, in 1817, has given the greatest satisfaction, and already produces considerable crops of grapes.

2655. The pine-pit of Scott (fig. 441.) will fruit 120 plants, with three or four chaldrons of coals. The bed for the plants is fifty feet long, and seven feet six inches wide; its peculiarities are that there is only a flue in front (fig. 441. a.), which returns on itself, and requiring no glass over it, is covered with flag-stone (b), supported by props of brick work (c). Covering the flue with flag-stone, Scott considers a great saving; it is less costly than glass, and as the part that it covers requires no heating, by using it, instead of glass, the lights are reduced to a more
PRACTICE

but the vine-walls this down forcing-frames years with feet low they adopted the and gardener be behind, of The and hind, of the rafters situated 506 formed buildings which returns this winter managed to most feet, or ten times, generally ten winters. As use the most twenty-five or thirty feet long, about five feet wide at bottom, and at the top about three feet. The height generally about ten feet, which is that of the wall against which they are placed. The fire-place is at one end, and the flue runs along the bottom to the opposite end, and generally returns to a chimney built in the middle of the frame. The vines are brought down from the wall, and nailed all along the front close to the glass frames, and are securely covered at nights. The black and white sweet-water are the kinds preferred for this early forcing. As this kind of forcing spoils the vines, it is necessary to have the vine-walls at least five times the length of the frame, in order to furnish a succession of well-perfected wood. After the crop is over, therefore, the vines in the course of the ensuing winter are cut down nearly to the bottom, and they require a term of four or five years to recover themselves for another early crop. (Tr. on the Vine, p. 127.) Similar forcing-frames heated by a bed of dung within, have been adopted by P. Lindegaard, gardener to the king of Denmark. (New Method of forcing Grapes, &c. 8vo. 1817.)

Sect. II. Of the Construction of the Vinery.

2656. The vinery affords the greatest latitude of construction; for the fruit-tree the most easily cultivated of all that are grown under glass, is the vine. For a crop which is to be forwarded by the natural influence of the sun, chiefly or alone, almost any form will suffice, provided the plants are trained near the glass. For very early crops, small houses with steep roofs (figs. 443, 444.), in order freely to admit the sun in the winter and spring months, are most desirable, and the section (fig. 443.) of the steep-roofed house used by the Dutch, is not surpassed by any form adopted in this country. It is commonly supposed that pits are the best buildings for early forcing, and as far as respects artificial heat, they are not much inferior to the Dutch vinery; but as to light, without which forced productions are not worth using, they are, from the low angle of their roof, greatly deficient. A house for early forcing (fig. 444.) may be thirty feet long, eight feet wide; the glass (a) twelve feet high, placed at an angle of 15° to the perpendicular; the flue entering at one end (f) may pass under the front glass (b), and afterwards make two or three returns in the back wall (d); the vines may be trained on a trellis nearly parallel to the glass, between the flue and the back wall (c), and the shed behind may be fitted up with shelves (e), and used as a mushroom-house. Such a house, being small, will be very easily managed in the most severe winters.

2657. The vineyards made use of by the Dutch for early forcing are generally about twenty-five or thirty feet long, about five feet wide at bottom, and at the top about three feet. The height generally about ten feet, which is that of the wall against which they are placed. The fire-place is at one end, and the flue runs along the bottom to the opposite end, and generally returns to a chimney built in the middle of the frame. The vines are brought down from the wall, and nailed all along the front close to the glass frames, and are securely covered at nights. The black and white sweet-water are the kinds preferred for this early forcing. As this kind of forcing spoils the vines, it is necessary to have the vine-walls at least five times the length of the frame, in order to furnish a succession of well-perfected wood. After the crop is over, therefore, the vines in the course of the ensuing winter are cut down nearly to the bottom, and they require a term of four or five years to recover themselves for another early crop. (Tr. on the Vine, p. 127.) Similar forcing-frames heated by a bed of dung within, have been adopted by P. Lindegaard, gardener to the king of Denmark. (New Method of forcing Grapes, &c. 8vo. 1817.)
2658. The vineyard of Speedley consists of a roof, and glass lights covering a border of about ten feet wide on the south side of a flued wall, about 14 feet high. Upright glasses, two feet and a half or three feet high in front, to support the roof, are used for vines to be forced at an early season, because it admits the sun and light to the border; but when grapes are not wanted at an early season, a considerable expense may be saved by adopting a low wall in front. The shade of this wall would be injurious to the border, if the vines were to be forced after the vernal equinox. I mention this circumstance, because some persons who give designs for buildings of this kind, lay so great a stress on this point, as to pronounce a vineyard or peach-house incapable of answering the intended purpose, should the pitch of the roof happen only to vary a degree or two from their favorite angle. In Holland, the frames for winter forcing are almost perpendicular, but for those forced in summer, they are almost as flat as those made use of for melons. Hence it follows, that the construction of different frames or buildings, for the purpose of producing grapes, should not only vary according to the quantity required, but also according to the season in which that fruit is intended to be produced. The roof should be steep for early forcing, and flatter for the summer. (Pr. on the Vine, p. 99.)

2659. The vineyard of Nicol for early forcing, to be commanded by one furnace, should not much exceed thirty feet in length. If it were forty or forty-five feet long, it would require two furnaces to be placed, and the roof as above described, the width of the frame may be ten or even fifteen feet, and the height thirteenth or fourteen; the front, including parapet and glass, not exceeding four feet in height. But, if the roof were made to rest on the parapet, without having any upright glass, and if the parapet were about eighteen inches high, it would have a better pitch, and there would be a longer run for the vines. The front flue should be two feet clear of the parapet, should return in the middle of the border, and double by the back wall, being separated from it by a three-inch cavity; that is, in the case of there being but one furnace for the house. But if the house be much above thirty feet in length, and require two furnaces, one should be placed at each end, in the shed behind, and the power of both should be brought to the front; the flue of the one to be placed within those of the parapet, and of the other close behind the first, being separated by a two-inch cavity only, and both to stand on a common foundation. The one may return in the middle of the house, and the other by the back wall; but it will be unnecessary to have a double return to either of them, as a house of the above-mentioned width and height, to the extent of fifty feet in length, may thus be fully commanded.

2660. The vineyard of Nicol for late forcing may be of any convenient length, from thirty to fifty feet; fourteen feet wide, and fifteen or sixteen feet high; with or without front glass, as above hinted. But if it have upright glass, both glass and parapet should not exceed five feet in height; as it is but seldom that any fruit grows below the angle of the rafter; and, if it do, it is never so well ripened as the fruit growing under the sloping sashes. The flues may be conducted, in every respect, as above directed for the early house, and the number of furnaces must be regulated by its length. If under thirty-five feet, one furnace may do; but if longer, it will require two furnaces, in order to have a perfect command of the temperature necessary for grapes. The parapet and front flue of both these houses should stand on pillars, three and a half feet deep under the ground-level, in order that the roots of the plants may have free scope to run to the border without the house; as the intention is to plant them inside, and train them, under the roof, to a trellis fixed to the rafters.

2661. Vineyards of other horticultural architects. Hay seems to make very little difference in the slopes of glass roofs for whatever purpose the house may be intended. In his very extensive designs for Lundie and the Scotts (Fig. 185) the differences are considerable. The same may be remarked of most of the ranges of houses built by G. Tod. (Ed. Engr. art. Hort.; Tod's Plans for Hot-houses, &c. Vol. 1812.)

445

2662. A vineyard for a crop to ripen in July. Knight recommends to be roofed at an angle of 55°, Wilkinson (Hort. Trans.) and Miller (Dict. in loco), 45°, which is that adopted most commonly for summer crops, both of grapes and peaches. Abercrombie says, 'The diagonal side of a glass case, designed for a short periodical course of forcing, to begin the 21st of December, may be 55°; 22d January, 50°; 21st February, be March, 47°.' He adds, 'Too much importance must not be attached to the angle of inclination in the glass work.' It is of some consequence to remark, that the roofs of vineyards may be fixed, provided there be shutters in the front and back wall for ventilation, though for these, as for every description of house, gardeners prefer a roof in which the sashes slide, are raised up, or take off. A vineyard on the curvilinear principle, with a fixed roof (reserving Fig. 185), was erected from our designs at Finchley, in 1818; no form or manner of construction can admit more light. The vines are trained within a foot of the glass; ventilation effected by shutters in the front and back walls, and the whole is managed by one fire. It is a beautiful object, the vines have grown admirably, and in 1820 produced a small crop (their first) of highly flavored fruit. Several other curvilinear-roofed vineyards have
been recently erected with iron roofs, and from their decided superiority in admitting light, we have no doubt of curvilinear iron roofs being ultimately adopted, not only for vineries, but for every description of hot-house, as soon as the great importance of light to vegetation, and especially to the flavor of fruits, is fully understood by practical men.

**Sect. III. Construction of the Peach-house.**

2664. *A peach-house not intended for early forcing*, may be of any shape, provided that the trees are either standards or trained near the glass. Knight and many practical gardeners are of opinion, that the roofs of all peach-houses should be made to take off, in order to color the fruit, and afterwards expose the trees to the weather for the sake of destroying insects.

2665. *In Holland, peaches are often forced in deep frames* (fig. 446.), filled within a foot or eighteen inches of the glass with tan (a), and heated by an exterior lining if necessary. The tree is planted in a box (b), by which its roots are confined so as to benefit by the heat of the tan, and the branches are trained on a trellis (c), close on the bed. Instead of tan, dung may be used, covered in the flowering season with earth, or tan and earth. In such pits peaches are ripened in Holland, by the middle of May. (*Hort. Trans.* v. 325.)

2666. *In Denmark, peaches are forced by dung-heat;* the tree is planted against the back wall (fig. 447 a.) which is heated by a lining of dung (b), as are its roots, and the area of the house by another lining (c). (*Lindegaard in Hort. Trans.* v. 320.)

2667. *The peach-house of Nicol for the earliest forcing,* to be commanded by one furnace, may be of any length, between thirty and forty feet; eight or nine feet wide, and twelve feet high. It should have no upright glass. The parapet may be about eighteen inches in height, and the rafters should rest immediately upon it. The intention here is, to train the peaches and nectarines up the roof, in the same manner as vines, only a little nearer to the glass, and none against the back wall. The front flue may run within two feet of the parapet, and should return by the back wall, being separated from it by a three-inch cavity. The parapet and front flue must stand on pillars, three feet deep under the ground-level, in order to give full scope to the roots of the plants.

2668. *A succession peach-house* to the above, that is, not to be forced so early, may be of a like length, ten or eleven feet wide, and thirteen or fourteen feet high; also without upright or front glass, and otherwise may be constructed in all respects as above.

2669. *A late peach-house,* to be managed by one furnace, may be forty or forty-five feet long; thirteen or fourteen feet wide, and fourteen or fifteen feet high. It may either have, or not have, upright glass in front; which should not, however, exceed four, or four and a half feet in height, including the parapet. The flues may be conducted as above specified for the early houses. The intention here is, to train plants on trellises against the back wall, and likewise half way up the roof, in the manner of vines; so that it may be termed a double peach-house.

2670. *The peach-house of M'Phail* was made sixty-four feet long, ten feet wide; the height of the back wall was four feet, and that of the front five feet. In pillars of brick work four feet each in length, which supported the sill to support the frame for the lights to rest upon; so that there were in the front eight vacuities in width, four feet each between the said pillars, for the roots of the trees to extend into the border. *In the inside of the pit, I had a wall built the whole length of the pit, and thirty inches distance from the front pillars. The wall was nine inches thick, and three feet six inches high, about one foot lower than the pillars of brick. I then made a border of good loamy earth, mixed with some very rotten dung, four feet deep, which left a vacancy between the pillars and the sill of nearly one foot, which was filled up with the earth of the border, which reached to the nine-inch wall within the pit, so that*
thirty inches wide of the border was in the inside of the pit. I had the border made fourteen feet wide."

"I got the floor of the pit paved with bricks, and in the back side, between the pavement and the trees, there was between five and six feet, so that a person had room to walk under to prune and manage the trees." The door was made in the back wall, at the west end; and at the east end a fire-place was made in the back wall, about three feet high, without a return. M’Phail began to force in the middle of March, and ripened abundant crops of fruit in the month of July.

2671. As a suitable peach-house, for early forcing, we would suggest a length of forty feet, width eight feet, and height twelve feet: the glass in two planes, each plane forming an angle with the perpendicular of fifteen degrees, and formed into sashes (fig. 448. a) hinged at their upper angles, and opening outwards. The flue (d) entering the house at one end (c), passing under the front glass, and making two turns in the back wall; and the trellis (e, b) placed between the flue and back wall. Such a house will be easily managed, and, like the early vinery, may be covered by mats in front during the most severe nights of winter.

2672. As a peach-house for a main crop, we would suggest a polyprosopic roof, with the sashes (fig. 449. a) opening on the principle of Venetian blinds; the flue (d) may pass round the house, and the trellis (c) be placed between the flue and front glass; both the flues and front glass may be supported on cast-iron props (e). The length may be forty feet, breadth and height twelve feet.

2673. Peach-houses and vineries combined. It is a common practice to combine the vinery and peach-house, and to train the vines close under the glass, and the peach-trees against the back wall (fig. 450. a); or to train the peach-trees against the back wall, and also on a flat or table trellis, in the middle of the house (b); but if the house be wide, neither modes are advisable, on account of the distance of the plants from the glass; and even in narrow houses, it can only be considered as a temporary expedient till the vines cover the roof. So important is light to every kind of plant, that, in our opinion, the vine should be very sparingly introduced even in pineries, where some plants are generally trained close under the roof (c), and where some gardeners think their shade beneficial.
Sect. IV. Construction of the Cherry-house and Fig-house.

2674. Any form will answer for a cherry-house. Some market-gardeners grow them in houses placed south and north, glazed on all sides, as Andrews at Lambeth; others in pits, and some in moveable glass cases.

2675. The cherry house of Nicol, to be worked by one furnace, may be from thirty to forty feet in length; from ten to twelve feet wide, and twelve or fourteen feet high. The parapet a foot or eighteen inches, and the front glass two feet, or two and a half feet high. The front flue to stand on the same foundation with the parapet, and its return to be by the back wall; but both flues to be separated from the walls by a cavity of three inches. The front parapet and flue to stand on pillars; which pillars should be thirty inches deep under the surface; the depth, or rather more than the depth requisite for the border. 'The back wall to be trellised for training cherries to; and the border to be planted with dwarf-cherries, or with dwarf apricots and figs, or with all three. The front and end flues to be crib-trellised, (i. e. shelves of lattice-work to be placed over them,) for pots of strawberries, kidneybeans, or the like.

2676. The fig-house may be of any form not very lofty. One constructed like the cherry-house, Nicol considers, will answer "perfectly well. The figs might be trained to the trellis at back, and either dwarf figs, apricots, or cherries, or all of these, might be planted in the border." As figs are not a popular fruit in Britain, a sufficient number for most families may be grown in pots and tubs, placed in the other hot-houses.

Sect. V. Of Constructing Hot-houses in Ranges.

2677. The culinary hot-houses are very frequently placed in a range, by which it is supposed something is saved in the expense of the ends, some heat gained, and greater convenience of management obtained. Nicol practised this mode, and Hay, as we have seen (fig. 445.) has adopted it at Dalmeny Park, Lundie, and other places. The same plan seems to be followed by Tod, of which, as an example, we may refer to a very substantial range (fig. 451.), constructed for the Honorable Champion Dymoke, at Scrivelsby. One of the most ornamental ranges of this sort in the neighborhood of London, is that of the Duke of Devonshire at Chiswick; but it is also the most gloomy within, of any we have seen. If we may submit our opinion, we should, in most cases, recommend detached houses (as in fig. 262.), in which opinion, we may add, Knight coincides.

Sect. VI. Construction of Culinary Pits, Frames, and Mushroom-houses.

2678. Culinary pits may be constructed either with or without flues; and either of such a height behind as to admit of a walk; or, so low, as to be managed like a common hot-bed frame. The intention of these pits, as far as culinary gardening is concerned, is first to force fruit-trees, as peaches, grapes, cherries, figs, apples, &c. in pots; and in this case the design which admits of a passage behind from which to water and manage the plants, will be found preferable; and secondly, to force strawberries, kidneybeans, potatoes, asparagus, sea-kale, rhubarb, &c. for which a pit sunk in the ground, and to be managed from without, will suffice, and is even preferable, because the plants may be brought close under the glass.

2679. The pit for fruit-shrubs may be forty feet long, eleven feet wide, within walls; the angle of the roof from 15° to 20°; the back path two feet wide, the furnace placed at one end, and the flue passing along the front, separated by a three-inch vacuity from the tan-bed, and returning close under the back wall. These dimensions will give a bark-bed six feet wide, thirty-seven feet long, and, supposing the surface of the pit to be kept level, it may be raised to any convenient height, according to that of the trees to be forced. Whatever be the height to which the pit is raised, the back of the pit should always be at least three and a half feet higher than the front, which will admit of different sizes of trees. The sashes for this pit may be in two lengths, one sliding over the other, as in hot-house roofs; but a better plan is, to have them to rise in the manner recommended for an early peach-house. (fig. 449.)
2680. The pit for forcing herbaceous vegetables may be in all respects of the same dimensions as above, but with the angle of the glass not more than 15°. On this plan and angle, the back of the pit will be two feet higher than the front: but the simplest plan is to omit the passage, and lessen the width of the pit two feet, retaining the slope of 15°, and the compound, or double sashes, between each rafter.

2681. Pits without fire heat, to be worked by that arising from the bed of bark or dung, may be of any length, six or seven feet wide within, and with the glass at an angle of fifteen degrees.

2682. M’Phail’s pit is approved of by many gardeners for growing cucumbers and melons, and may be considered as coming into general use. Abercrombie, after describing it as a “flued pit without a furnace,” says, “some persons approve of this kind of frame, and others disapprove of it; but when the management of the air-chamber is understood, it may be applied very successfully to the forcing of early melons and choice esculents. It allows new stable-dung, even before any of the fiery particles are exhaled, to be used without any danger of burning the roots of the plants.” (Pr. Gard. p. 662.)

2683. Other pits and fixed frames. West’s pit (fig. 1547.) and the Alderstone fixed frame (fig. 1549.) are both structures deserving introduction where neatness is an object, and it is to be hoped that these and similar structures (see Hort. Trans. vol. iv. and v.) will soon come into more general use, and elevate the melon-ground from a disorderly dung-yard, to a scene fit for general inspection.

2684. Knight’s melon-pit (fig. 452.), and which may also be applied to the culture of cucumbers, young pines, or other low vegetables, is surrounded by a cellular wall, (see 1561.) The front wall is four feet, and the back wall five feet six inches high, enclosed a space of six feet wide, and fifteen feet long, and the walls are covered with a wall-plate, and with sliding lights, as in ordinary hotbeds. The space included may be filled to a proper depth with boxes of earth, where it is wished to promote the rapid growth of plants; Knight, however, did not use dung internally, but grew the melon-plants in large pots, and trained them on a trellis at a proper distance from the glass. The wall is externally surrounded by a hot-bed composed of leaves and horse-dung, by which it is kept warm, and the warm air contained in its cavity is permitted to pass into the enclosed space through many small perforations in the bricks. At each of the lower corners is a passage (a), which extends along the surface of the ground, under the fermenting material, and communicates with the cavity of the wall, into which it admits the external air, to occupy the place of that which has become warm and passed into the pit. The entrances into these passages are furnished with grates, to prevent the ingress of vegetable or other kind. The hot-bed is moved and renewed in small successive portions, so that the temperature may be permanently preserved, the ground being made to descend a little towards the wall on every side, that the bed in shrinking may rather fall towards than from the walls; and Knight entertains no doubt, but that the perpetual ingress of warm air, even without an internal leaf-bed, will prove sufficient to preserve pine-apple plants without the protection of mats, except in very severe weather.” (Hort. Trans. v. 224.)

2685. The Edmonstone pine or melon pit (fig. 452.) is eighteen and a half feet long, by six feet in breadth; the height of the back is five feet, the front three feet nine inches; the declivity of the glass one foot three inches. The pits for the dung are on the outside of the frames, and sunk level with the surface of the earth, or gravel, on the outside. The height of these pits is three feet, their breadth two feet. The outside of the pits for the dung is built with a nine-inch wall up to the surface, with one course of hewn stone on the top. One inch is cut out for the boards that cover the space allotted for the drying of the dung, which is so offensive in ordinary hotbeds is thus prevented. The boards that cover the dung are one inch thick, by two feet two inches in breadth. They are of the length of the pit, and have rings at each end for lifting them with. The pits are such as will drain well, to carry off the underground water, and a small grate should be made at the end of the drains. The kind of matter which is generally employed to fill these pits, is a mixture of new horse and cow dung; sometimes we use tree leaves and short grass, which do very well, provided they are duly prepared, by throwing them up in a high heap, to remain eight or ten days, that they may ferment to an equal degree. The dung is applied in a bed of about twenty degrees of heat; the horse and cow dung, or leaves of trees is no difficult matter, and it is easy to preserve the plants in health, and in a fruitful state during the severest winter, by covering the pits with mats in time of frost. (Caled. Hort. Mem. iii. 336.)

2686. The common hot-bed frame is generally from four to five feet wide within, and from nine to twelve feet long, divided into three or four lights or sashes. The back is generally double the height of the front, so that the slope of the glass is seldom more than ten degrees. Knight, with great correctness of principle, considers this as too flat to admit the sun’s rays in the winter season, and recommends a basis of earth sloped to
an angle of fifteen degrees, then forming on it the dung-bed, by which means its surface will be at the same angle as the base; and, lastly, he constructs the frame equally high, both in front and behind, and placing it on the dung, still retains the above angle. (Fig. 375.)

2687. The common form of the mushroom-house and that recommended by Oldacre have been described. (1694. and 1695.) The latter plan, though adopted in several places, does not appear to be so generally countenanced by practical, and especially by market-gardeners, as to justify our giving it a preference in this part of our work. In the greater number of cases where mushrooms are grown for the London market, they are raised in the open air on dung-ridges; and a number of gentlemen’s gardeners make use of back sheds, either closed, or open, and some of old cucumber-beds.

Sect. VII. Details in the Construction of Culinary Hot-houses.

2688. There are certain details of construction in glazed structures, on which from their novelty or rarity there is considerable difference of opinion among gardeners. These are chiefly metallic roofs, steam, furnaces, flues, trellises, and ventilators.

2689. Materials of the roof. In the construction of the roof, iron and copper, and other metals, have been lately introduced, in order to admit more light, and be more durable. This improvement, Abercrombie observes, “is at present too new to afford ground for a decisive opinion;” and Nicol says, “On account of the high price of timber, some are now constructing the framing of hot-houses of cast-iron. I would beg leave to remind such, that there is nothing so prejudicial to vegetation as the dripping of rusted iron; and would advise, that the frames be well and frequently painted, in order to prevent the bad effects of iron water falling on the foliage and fruit. I am of opinion, however, that iron-framed hot-houses will soon get out of fashion. From the quantity of water that must be used, in order to keep the plants in health, the frames must be often moistened, and will corrode.” Not only cast-iron rafters, but roofs entirely of iron have wonderfully increased since Nicol’s time.

2690. The mode of heating by steam is becoming very general in the neighborhood of the metropolis, and especially by such commercial gardeners as have extensive forcing departments, as Lodgdes, Gunter, Grange, Andrews, Wilmot, &c. and wherever there is a range of any extent, this mode seems far preferable to heating by smoke-flues. Nicol gives no opinion on this point; but M’Phail says, “At present, I must freely own, that I have some doubts both of the cheapness, and superiority in other respects, of this new scheme of forcing by the influence of hot water, over the generally adopted methods of the influence of fire, dung, and tan heat.” Even “if found to answer better than fire alone, which I much doubt, it will only, I apprehend, be adopted in gardens where there is much forcing, and therefore, of course, the more simple methods of forcing by fire, dung, and tan heat, will be continued in moderate-sized gardens and in small ones.” (Gard. Rem. p. 122.) Experience confirms the propriety of these remarks.

2691. The furnace used by Nicol is simply an oven, capable of containing less or more fuel, according to the kind of hot-house to which it may be attached, and the kind of fuel to be used, with a grate in front, just large enough to kindle the mass of fuel, and keep it alive. In one of a middle size, the oven is thirty inches long and twenty inches wide; the grate eighteen inches long and ten broad; the furnace-door ten inches square; the ash-pit door ten inches wide but fifteen inches deep, both with circular valves in their centres. The grate is placed close to the furnace-door. (Kal. p. 280.) Others have been tried, but none answer better for the general purposes of fuel hot-houses.

2692. Flues. Nicol gives the decided preference to flues constructed of brick and tiles, thus—“The sole of two-inch thick tiles, each fifteen inches long, by twelve broad; jointed on cross bricks on edge, or pillarets, to keep them about four inches clear of the surface. The walls of well-moulded, or stock bricks, six inches clear of each other, and the height of two bricks placed on edge, covered with inch and half thick tiles, each twelve inches long and ten broad, laid the length to the run of the flue, by which means the covers will not be flush with the sides of the flue, but each edge will be champhered or bevelled, which makes the flue look very light and neat. The open or void of the flue will thus be (with the height of two bricks on edge, and two joints of lime, ten by six inches, or thereby. It is clear, and detached on all the four sides, except the interruptions of the pillarets; and is the most effectual flue of many different sizes I have tried.”— Of air-flues, the same author observes, “I think I have ascertained the uselessness of air-flues.” Our opinion is that air-flues in most cases are more injurious than useful, and we believe there has been no mode yet discovered for issuing a current of heated air into a hot-house that is not liable to the most decisive objection on account of the risk of heating to excess. A mode of heating air by steam and then introducing it to the house is now disseminating by some London tradesmen under the name of calorifères, and which is particularly obnoxious to these objections.

2693. Trellising. “Rooftrellising,” Nicol observes, “is now universally of wire,
and often also that against back walls. It is cheaper than wood, and, on account of its lightness, fitter for the purpose, especially when placed on the roof, or against the end lights. The distance at which the wires should be placed apart for grapes, is ten or twelve inches; for cherries or peaches, four or five. The distance of the wires from the glass, for grapes, a foot; for peaches and nectarines, nine inches. But there should be a lower trellis, with the wires placed at two feet apart, and a foot under the proper trellis, on which to train the summer shoots of vines that are in a full-bearing state, in order that there may not be too great a confusion of fruit, shoots, and foliage. When vines are trained up the rafters in a stove or green-house, they should not be nailed to the beam; but three rows of wire should be extended for them, at the distance of four or five inches from each other, and three from the rafter; being set out with studs of wire, or of iron, made to screw into it, and with eyes to take in the wire.”

2694. Ventilators. "The hot-house may require to be ventilated at times, when it may be improper to open the sashes for that purpose. Ventilators are then useful. They may be contrived in different forms, and may be placed in different situations. If the hot-house have a shed behind it, they might be made to open, in the manner of a common window, near to the top of the back wall; and three in an ordinary-sized house would be enough. I lately made four ventilators in a house that had no shed behind it, in this manner: when the wall was raised to within a yard of its full height, apertures were formed in the manner of a common chimney or fire-place, eighteen inches wide, and two feet high, from which a small vent was carried through the coping. On the top was fixed a horizontal tube, three inches square, and two feet long, with a centre pipe fixed into the vent. The aperture or chimney was filled in front, with two moveable panels or boards hung in the manner of common sashes, the one to move up and the other down, for the admission of air through the tube at top, thus diverting or breaking a strong current, which might be prejudicial to the grapes. Ventilators in front, at the distance of six or eight feet from one another, may be made thus: Pierce a hole an inch diameter, through the bottom rail of the under sash if the house have no upright glass, or through the upper rail of the upright sash, if it have. In this hole insert a tin tube to fit, having a funnel mouth outwards, and a fine rose, like that of a watering-pot, to fit to it inside. The tube should be made in lengths of two feet each, that the air may be either diffused as it enters through the front, or be carried to the centre of the house, or farther if thought necessary. When not in use, it should be stopped with a cork or plug. When a full stream is wished, the rose need not be put on; but it should if the air be keen. In order the better to collect the air, the funnel should be pretty large; that is, about seven or eight inches diameter. With these and with the ventilators at or near to the top of the back wall, as mentioned above, any hot-house may safely be aired or ventilated, even in the severest weather; and also when it may be improper to open the glasses, as during rain.”

2695. Annual repairs. The best gardeners clean the flues, white-wash the walls, and paint the wood-work of hot-houses every year, or paint every other year. In general, once in four or five years may suffice; but every thing will depend on the purpose to which the house is applied; a system of early and severe forcing being evidently much more trying for the roof than moderate sun-heat, aided by occasional fires. The breakup of glass from frost amounts frequently, in the northern counties, to five per cent. on the surface of the roof, especially in flat green-houses, and others, where there is not a sufficient heat kept up to prevent the water from freezing in the unputtied interstices; but we know instances of pineries and other stoves where, for ten years, as many panes have not been broken. A roof at an angle of not less than 45°, diagonal or fragment glazing, or a closed lap, seem prevents to breakup in cold-houses: Stewart’s copper lap is still more effectual, but produces a dark, heavy effect, not at all suitable to hot-houses of any sort, and with difficulty admits of repairs. Our opinion is, that by using the best crown glass, small panes, and a lap of not more than one eighth of an inch, no breakup from frost will take place in any description of roof. If the work is performed in a masterly manner, closing this lap by putty, lead, or copper, will be unnecessary even for pineries or winter forcing.

Chap. VII.

Of the general Culture in Forcing Structures and Culinary Hot-houses.

2696. By general culture, we are here to understand the formation of the soil, the arrangement of the trees or plants, and their general treatment when planted, in regard to temperature, air, water, training, and other points of management.
2697. The pine-apple is a native of the tropical regions of Asia, Africa, and South America; and thus, from its original habitation and nature, it requires a higher degree of heat than any culinary or fruit-bearing plant at present cultivated as such. It is by no means, however, so delicate as many imagine; for as it will bear a higher degree of heat continued for a length of time than either the vine or the peach, so, at any period of its growth, it will bear, without injury, a degree of cold for a space of time which, though short, would have destroyed the foliage of a vine or peach-tree in a state of vegetation. "This incomparable fruit," Weeks observes, "can be obtained even in frames without fire-heat, having only the assistance of tan and dung; and is more easily brought to maturity than an early cucumber." Though liable to the attacks of insects, it is less so than the peach, and less speedily injured by them than the common cabbage. Diseases it has almost none. The pine is generally grown in pots, and plunged in a bed of Tanner's bark, or other matter in a state of fermentation; recently, however, it has been grown without bottom heat, and even with a lower atmospheric temperature than it has been accustomed to receive, at least, during winter; but as the experience of gardeners is very limited on this mode of treatment, we shall reserve whatever we have to offer on it, till we have brought into view the established practices. The fruit being reckoned the most delicious of all others, and gardeners being valued by the wealthy in proportion to their success in its cultivation, we shall here lay before the reader a copious view of the present modes of culture, from the works of the most respectable practical men who have written on the subject; noticing also, occasionally, the practices of those who grow them for the London market.

SUBSECT. 1. Varieties of the Pine and General Mode of Culture.

2698. The most esteemed varieties of the pine-apple for general cultivation are, according to Speeckhuy, the following, here arranged in the order of their merits:—

According to Abercrombie, they are the following:—

According to M'Phail, the pines most worthy of cultivation are—

According to Nicol, the kinds most generally cultivated in hot-houses are—

According to Griffin, the following varieties are recommended—

Baldwin, for expeditious forcing, on which alone he treats, recommends—

2699. Plan of culture. As the pine-plant is a triennial, bearing fruit once only, unlike the peach and vine, and other fruit-bearing plants, its propagation, rearing, and fruiting, are all carried on in every garden where it is cultivated. Its culture generally commences in a common hot-bed frame, heated by dung; at the end of a period varying from six to nine months, it is removed to a larger framed hot-bed, or pit, generally called a succession bed or house; and after remaining there from eight to twelve months, in conformity with circumstances, it is removed to its final destination, the fruiting bed, pit, or house. Here it shows its fruit, continues in a growing state during a period varying from six to twelve months, according to the variety grown, mode of culture, &c.; and finally ripens its fruit and dies, leaving the crown or terminal shoot of the fruit, and one or more suckers or side-shoots as successors. The production of a single pine-apple, therefore, requires a course of exotic culture, varying from eighteen months to three years, and generally not less than two years.

SUBSECT. 2. Soil.

2700. The pine-apple soil of Speeckhuy is as follows:—"In the month of April or May, let the sward or turf of a pasture, where the soil is a young rich loam, be cut off, and a square foot of it spread out, so as to form a bed one foot thick; let it then be carried to the pens in sheep-pastures, where sheep are frequently put for the purpose of dressing, which places should be cleared of stones, &c. and made smooth; then let the turf be laid in the grass side downwards, and only one course thick; here it may continue two, three, or more months, during which time it should be turned with a spade once or twice, according as the pen is more or less frequented by the above animals, who, with their urine and dung, will enrich the soil to a great degree, and their feet will reduce it, and prevent any weeds from growing. After the turf has lain a sufficient length of time, it should be brought to the place of its permanent position at least six months (if a twelvemonth it will be the better), being frequently turned during that time; and after being made pretty fine with the spade, but not screened, it will be fit for use. In places where the above mode cannot be adopted, the mixture made by putting a quantity of sheep's dung (or deer's dung, if it can be got) and turf together. But here it must be observed, that the dung should be collected from the pastures when newly fallen; also, that a larger proportion should be added, making an allowance for the want of urine. 1. Three wheelbarrows of the above reduced sward or soil, one barrel of vegetable mould from decayed oak-leaves, and half a barrel of coarse sand make a compost-mould for crows, suckers, and young plants; 2. Three wheelbarrows of sward reduced as above, two barrows of vegetable mould, one barrel of coarse sand, and one fourth of a barrel of sot, make a compost-mould for fruiting plants. The above composts should be made soon after the harvest, and if they are wanted at a very frequent time during that time, that the different mixtures may get well and uniformly incorporated. It is observable, however, that in hot-houses, where pine-plants are put in a light soil, the young plants frequently go into fruit the first season
Artificial Heat.

2701. Acerbicrombie's compost for the pine-apple is formed of the following articles: 1, vegetable manure, e.g. horse, cow, or vegetable mould; 2, hard, well-rotten, and mellowed by at least a year's preparation; 3, small, partly river-gravel; 4, white, sea-sand; 5, shell-marl. If no vegetable mould has been provided, light, rich earth, from a fellowed part of the kitchen-garden, may be substituted: there is no difference of any account between one and the other, furnishing the necessary supply of vegetable mould which the compost requires. For some, the mould from the kitchen-garden, however you may trenched, and, and enrich it, cannot but contain many particles which have given out their fertilising qualities to previous crops. Dung perfectly decomposed, but not yet entirely pulverized, will do, though one must be particularly cautious, or the compost will be liable to become sandey, and, if hard, or properly prepared, the coarser particles cannot pass the sieve. If there are many particles that are liable to occur in the compost, they should be sifted to separate them and keep them from entering the bed. Soot, if it be used at all, must be very well sifted, and the small particles of this substance thoroughly mixed with the compost to prevent it from burning the plants. It is not necessary to plough the earth to mix them, but a good deal of manure will be required in the compost.

2702. The soil for the pine-apple, recommended by M'Phail, is any sort of rich earth taken from a compartment of the kitchen-garden, or, if sandy loam taken from a common, long pastured with sheep. &c. If the earth be not of a rich sandy quality, of darkish color, it should be mixed well with some perfectly rotten dung and sand, and if a little vegetable mould is put among it, it will do it good, and also a little soil with plant-remains. Though pine-plants will grow in the strongest earth, yet I have found by experience that they grow most freely in good sandy loam not of a binding quality.

2703. The soil for the pine, used by Nicol. In this, vegetable mould being a chief ingredient, a stock of it should be provided wherever the culture of the pine is followed. The kind to be used here is that from deep loam, as that portion of the earth which is less subject to be preferred; but when a sufficient quantity of them cannot be had, a mixture with those of the ash, elm, birch, sycamore, &c., or indeed any that are not resinous, will answer very well. In autumn, immediately as the leaves fall, let them be gathered, and be thrown together into an heap; and let just as much light earth be thrown over them as will prevent them from fermenting. In the spring, let them be gathered up, and the heaps made of them, and then mix them well. They will be rendered into mould fit for use by the next spring; but from bits of sticks, &c., in which they are, they will require to be sifted before using. Strong brown loam is the next article. This should be taken from the bottom of a pasture, which is exposed to the action of the weather. Pigeon-dung, also, that has lain at least two whole years in a heap, has a peculiar turn, and exposed well to the weather, is to be used. Likewise shell-marl. And, lastly, sea or river gravel, which should be sifted, and kept in a dry place; such part of it as is not used, which is the greater proportion, is to be used. This is the proportion: for crowns and suckers, entire vegetable mould, with a little gravel at bottom, to strike in; afterwards, three fourths vegetable mould, and one fourth, mixed with about a twentieth part gravel, and two inches entire gravel at bottom, till about a year old. For year-olds, and till shifted into fruiting-pots, one half vegetable mould, one half gravel, and a quarter of the gravel at bottom; and for fruits, gravel at bottom. For fruiting plants, one half loam, a fourth part vegetable mould, and a fourth part gravel-pot; to which add marl and gravel as above, and lay three or four inches of clean gravel at bottom. A similar proportion of materials is used for the above composts and others, I formerly used for pine-plants with much success; and are what may be reckoned good medium soils for the production of pine-apples.

2704. Griffin's pine-apple soil is free from many different strange ingredients for composts recommended by others; for after numerous experiments made with mixtures of deer's, sheep's, pigeons', hens', and rooks' dung, &c., in various situations and combinations with soils of different qualities from pastures and waste lands, I can venture with confidence to recommend the following: Procure from a pasture, or waste land, a quantity of brown, rich, loamy earth, if of a reddish color the better, but of a fatty mouldy temperature; that by squeezing a handful of it together, and opening it, it should not be so easily done as to cause much shock deep, with three or four grains of that pliable texture; likewise procure, if possible, a quantity of deer's dung: if none can be conveniently got, sheep's dung will do, and a quantity of swine's dung. Let the above three sorts be brought to some convenient place, and laid up in three different heaps, ridge-ways, for at least six months; and then mix them in the following manner, covering the dung with a little soil before it is mixed: four wheelbarrows of the above earth; one barrow of sheep's dung, and two barrows of swine's dung. This composition, he adds, "if carefully and properly prepared, will answer every purpose for the growth of pine-plants of every description. It is a compost which is hardly comprehended, and will be found to be of the advantage of the summer's sun and winter's frost; and it need not be screened or sifted before using, but only well broken with the hands and spade, as when finely sifted it becomes too compact for the roots of the plants." (Tr. on the Pine-app, p. 305.) Baldwin's soil for pine-apples is still more simple than Griffin's: "From old pasture or meadow ground strip off the turf, and dig to the depth of six or eight inches, according to the goodness of the soil; draw the whole together to some convenient place, and mix it with one half of good rotten dung; frequently turn it over for twelve months, and it will be fit for use. This is the only compost-dung for young and old plants." (Cult. of Ananas, p. 8.) Week's soil agrees with Baldwin's: he takes unhaunted earth and some rotten dung, and gives them a twelve month's preparation, by turning and mixing previously to using. (Forcer's Assistant, p. 50.)

Subsect. 3. Artificial Heat.

2706. Bottom heat. The pine, when originally introduced in England, was, without bottom heat, on stages, like other succulents. Inengenuity, however, soon suggested, and experience approved the advantage of the latter, first in preserving a moist equable heat; and, secondly, in preventing the plants from feeling so much as they otherwise would any casual declension in the fire-heat, or sudden vicissitude in the temperature or moisture of the external air. "Pines," Nicol observes, "do certainly not require so strong a bottom heat as many keep them in; yet there is something in a mild tan heat, so congenial to their natures, that they thrive much better in pots plunged in a barkbed, if properly managed, than when planted out on a bed of earth that is heated, and often scorched, by under flames." The tan or bark pit is therefore considered essential to the pinery.

2707. Bark-pits are filled with tan which has previously undergone a course of draining and sweating. The heat thus produced, will last from three to six months, when it is sifted and again put into a state of fermentation, by replacing the deficiency occasioned I. 1 2
by decay, and separation of the dust by sifting with new tan. In this way the bark-bed is obliged to be stirred, turned, refreshed, or even renewed several times a year, so as to produce and retain at all times a bottom heat of from 75 to 85 degrees in each of the three departments of pine culture. These operations being common, we have placed a summary of management under the head of General Directions for the Bark-pit, at the end of this section. (See Subsect. 8.)

2708. Dung-heat. Pines are grown to the greatest perfection by many gardeners without either bark or fire heat simply by the use of dung. A frame double the usual depth and also about a third part broader than the common cucumber frames, is placed on a bed of dung, or of dung and tan, or dung and ashes, or even dung and faggots mixed or in alternate layers. This bed of itself supplies heat for a while, and when it begins to be exhausted, linings are applied in the usual way, and continued for a year or more, reviving and renewing them as may become requisite, till the bottom bed becomes too solid for the ready admission of heat. The frame and pots are then removed to a prepared bed, and this old bottom taken away, or mixed up with fresh materials. In this way, as Weeks observes, every one that can procure stable-dung may grow pines. In a tract On the Ananas and on Melons, by A. Taylor, printed in 1769, the author tells us that he both rears and fruits pines in a pit formed of boards or of brick-work three feet deep, and of any convenient length and width; and on the walls or boards which enclose the tan, he places a frame two and a half feet deep in front, and four feet high behind. The ends and front are of glass, and the latter is formed into small sashes, which slide in a groove. The back is formed of inch boards; and against these he places a powerful lining of dung. The pit he fills with tan, or dung, as may be most convenient; “dung,” he says, “does as well as tan and only requires a little more trouble, which is amply repaid to the gardener by the value of the dung to the garden, when no longer in active fermentation.” An anonymous annotator (to the copy of Taylor’s book, in the library of the Horticultural Society) says, “I find by experience, that the dung of four horses is sufficient to work two frames twenty-six feet each in length, and six in breadth; one for the fruiting-house, the other for succession plants; and that it may be reasonably expected to cut forty fruit yearly after the first year, and that dung as valuable for the field or garden, as if this use had not been made of it.” (Taylor on Ananas, &c. p. 3; Diff. Modes of Cult. P. App. &c. p. 47.)

2709. Fire-heat for the atmosphere. The high temperature requisite for the pine in every stage of its growth, renders it necessary to have recourse to fire-heat for eight or nine months in every year; unless indeed the plants are grown in pits heated by linings of dung; in which case, these linings become necessary every month in the year in order to keep up the bottom heat. What respects the management of fires being also common to the culture of this plant in all its stages, we have placed the directions as in the case of bark-pits under such as are general. (See Subsect. 8.)

2710. Dung-heat and fire-heat combined. Jenkins, of the Portman nursery, London, grows his pine-plants in large hot-beds, and fries them in a house (fig. 454), which “though furnished with flues, yet these have been very little used. The heat imparted to the plants is produced by the fermentation of stable-dung in a pit below the plants, the top of which is covered by tiles supported by iron rafters, with the joints closely cemented, to prevent the passage of steam into the house. The pots are neither bedded in tan, nor in mould, but stand on the tiles, and the interstices between them warm the air of the house. The dung is managed as in West’s pit, but with the addition of being watered after it is thrown in, which is found to promote fermentation, and the intensity of the heat. (Hooker, in Hort. Trans. iv. 985.)

2711. Steam-heat, with or without any of the other modes of heating, has been tried extensively as far as respects heating the air of the house, and with the most perfect success. As a bottom heat it has also been tried in different places by turning it into vaults of air, or cisterns of water, or chambers of large rough stones (which imbibe the heat and give it slowly out to the bed above) with different degrees of success, but not such as to induce cultivators to relinquish fermenting substances in its favor, where they can be procured at a reasonable expense.

Subsect. 4. Propagation of the Pine-apple.

2712. The pine is generally propagated by crowns and suckers, though, in common with every other plant, it may be propagated by seed. Speechly prefers suckers, because ge-
nerally larger than crowns, and those produced near the middle of the stem, he considers the best. He does not, however, reject crowns; but selects the largest, which he says, when nine inches in circumference at their bottoms, equal any suckers. (Treatise on the Pine-Apple, 2d edit. 22.) Abercrombie says, “Suckers which rise from the extremities of the roots, at a distance from the stem, though they have radical fibres, are apt to have ill-formed hearts. With Speechly, he prefers stalk-suckers and strong crowns.”

(Proct. Gard. 621.) Andrews uses suckers only, not from any objection to crowns, but from the difficulty and trouble of getting them returned from the fruiterers, and the risk of different kinds of being mixed through the carelessness of servants. M’Phail, Nicol, Griffin, and Baldwin, do not express any preference.

2713. Separation of crowns and suckers. Speechly and Abercrombie concur in the following directions: “With a knife, detached by a gentle twist, and returned, by the gardener, if it be wanted for a new plant. Fruit-stalk suckers are separated at the same period. Such suckers, at the base of the herb are commonly fit for separation when the fruit is mature; though, if the stool be vigorous, they may be left on for a month after the fruit is cut, the stool receiving plentiful waterings on their account. The fitness of a sucker to be removed is indicated, at the lower part of the leaves, by a brownish tint there; on the appearance of which, if the lower leaf be broken off, the sucker is easily distracted by the thumb.” Speechly says, “Suckers cannot with safety be taken from the plants, till they are grown to the length of twelve or fourteen inches, when their bottoms will be hard, woody, and full of small round knots, which are the rudiments of the roots. It would endanger their breaking, if they were to be taken off sooner. When the suckers are taken off, the operation should be performed with great care, that neither plant nor sucker may be injured. To prevent which, one hand should be placed at the bottom of each sucker before it is detached from the stool; the sucker should be torn gently out; after which, the sucker should be moved two or three times backwards and forwards in a sideways direction, and it will fall off with its bottom entire. Whereas, when a sucker is bent downwards immediately, the plant, it frequently either breaks off in the stem, or splits at the bottom.” Andrews allows the suckers to be taken off on the parent plant, till they have attained a large size; sometimes even till they are fit to occupy a large pot at once.

2714. Season of separating crowns and suckers. Crowns and suckers taken off from the parent plant later than October, should not be planted before the month of February or March; for, in the winter time, productive young suckers may be thus injured, sterile, dry plants, or suckers. Where mature young suckers and crowns should lie unplanted, till their natural juices be so exhausted that there may be no danger of their rotting after being planted; but if they are grown to such a size as to be easily separated from the parent plant, they may be planted immediately. (Gard. Rem. 63.)

2715. To generate suckers. If the old fruiting plant offers only small bottom-suckers, or fails to furnish any, you may bring out good suckers thus: Having waited till the fruit is cut, take the old plant out of its pot in the barb-bed; strip off the under leaves near the root, and with the knife cut away the leaves to six or eight inches, allowing the stump to be made quite smooth. Fix the stump firmly on the pot, filling it with fresh compost, if the latter be allowed; water it freely; place it in a dark place, or in a warm place, and keep it from light. Plunge the old plant into a bed with a good growing heat. Let the routine culture not be neglected, and the old plants will soon send out good suckers. Allow these to grow till they are four inches long or more; and on the signs of fitness, detach them.

2716. Preparation of suckers or crowns. As soon as the crowns or suckers are detached, twist off some of the leaves about the base; the vacancy thus made at the bottom of the stem is to favor the emission of roots. Pare the stump smooth; then lay the intended plants on a shelf in a shaded part of the stove, or in the green-house, or of any dry apartment. Let crowns and fruit-stalks lie till the part that adhered to the fruit is perfectly healed; and root-suckers in the same manner, till the part which was united to the old stock is come dry and firm. They will be fit to plant in five or six days. As to the prolonged months the plants have been kept out of mould, in a moderate dry season, it is not always necessary, to delay them more than six weeks, if they are well watered. Michaelmas should be planted. Without any unnecessary delay, to get established before the winter. When late-fruiting plants do not afford offsets till after Michaelmas, it is best to keep them in a dormant state during the months least favorable to artificial culture; therefore, as you obtain these late offsets, hang them up in the house, not too near the fires, to rest till Michaelmas. Some think it necessary to dry, or win, all crowns and suckers before potting them, and for that purpose lay them on the shelves, &c. of the stove for a week or ten days. By this treatment, they certainly may be hurt, but cannot be improved, provided they have been fully matured before being cut or detached.” (Gard. Rem. 63.) These have previouly been much recommended. They will succeed as well if planted the hour they are cut, as if preserved for about a month; but they should be treated in any other way whatever; and I only advise their being laid aside as above, being a matter of convenience. (Nic.)

2717. Planting crowns and suckers. Nicol plants his suckers in summer and autumn as the fruit is gathered, staking them into the front part of the bark-bed, “where they will strike root as freely as any where. If a large proportion of the crop come off early, the crowns and suckers may be potted at once, and plunged into the nursing-pit; or they may be twisted from off the stocks, and may be laid by, in a dry shed or loft for a few days, till the other operations in the nursery be performed, and the nursery-pit be ready to receive them and the crowns (collected as the fruit have been gathered); which, if rooted, may be potted, and may be placed for the above time, in a frame, or in a forcing-house of any kind, as they will strike root, and the only hindrance for so doing is, the suckers being too soft, or not long enough. Such crowns or suckers may be laid aside with the suckers.” Griffin generally plants his crowns in the bark till they are quite struck root; but the suckers he pots at once, unless they are small and green at bottom, when he treats them like the crowns. Baldwin says, “Towards the end of September, take off the suckers from the forcing-house, and lay them in a warm place for about three days; then strip off a few of their bottom leaves, and they will be ready for planting. Plant them in the old tan, on the surface of the bed, without pots, about four or five inches apart, according to the size of the plants; observing, that the tallest is placed at the back of the frame, and the shortest in the front. In this state let them remain till the following spring.” (Gard. Rem. 63.) Andrews pots his suckers in September, and plunges them in a bark-bed during the winter.

Subject. 5. Of rearing the Pine-apple in the Nursing Department.

2718. The rearing of the pine-apple requiring different modes of treatment at different stages of its progress to maturity, established practice has adopted three houses or pits, through each of which the plants pass in succession. They are usually named the nursing, succession, and fruiting houses, or pits. The nursing-pit is used for bringing on crowns and suckers until they are established in growth, and for this purpose they generally remain there one year.
PRACTICE of GARDENING. PART III.

2719. Nursing-pit with fire-heat. The nursing-pit is generally flued, but some adopt a common dung hot-bed, and others the flued pit or bed recommended by M'Phail, and which answers extremely well. The minimum depth of the bark-bed in the nursing-house, Abercrombie states, to be three feet; "the maximum three and a half. The less depth is the right, when bark alone is employed to promote the heat and make it the greater, when tree-leaves are used to increase the heat and prevent too great a surface influence. In either case, the pit may be six inches shallower than that in the fruiting-house; because the requisite altitude in the different parts partly depends on the perpendicular dimension of the pots, and on the thickness to which a layer of fresh dung is applied. If the surface is too close, the leaves of the trees, instead of being used to advantage, the roots may not be burnt. In the nursery-pit, the neutral layer need not be deeper than eight inches." "If the bark-bed has been in action to bring forward a previous set of plants, now removed to the succession-pit, it is usually done by taking away the wasted bark, to the extent of a sixth, fourth, third, or half part, and by substituting an equal quantity of fresh. A lively bottom heat is requisite to make pines offsets strike freely.

2720. Some growers of pines, he adds, "who cannot command higher means, choose to cultivate crowns and suckers in pits without flues. As the aid of the furnace, however, allows of this, and the latter often prevents the necessity of covering the glasses in very cold days, it is not to be deliberately rejected from the nursing-pit, when new buildings, or fundamental alterations, are in agitation—unless the vicinity of some large establishment for horses should offer a regular supply of dung, without much expense of carrying it. Then, and only then, should the pit be flued, or tree-leaves is always to be preferred, in combination with flues."

2721. Speedily adopts the flued pit, and occasionally the frame, but generally a part of the succession-pit. Nicol the nursing-house. Griffin adopts three houses, the two last diminutives of the first, which is that of the larger. Nicol, in the analysis of Abercrombie, Baldwin makes use of a succession or nursing bed, without fire-heat, and of a fruiting-store, both small.

2722. Nursing-pit, without fire-heat. "Hot-beds used for growing suckers," Speedly observes, "should be well prepared, and the violence of the heat allowed to be fully over before the suckers are taken off. It is then to be levelled and covered with eight or ten inches of tan, into which to plunge the pots." (Treat. on the Pine, 34.) M'Phail, who, when gardener to the Earl of Liverpool, was reckoned one of the best pine-growers in England, recommends the brick bed of his invention as answering well for small succession-plants. "A pit," he says, "built on the same construction, but of larger dimensions, without cross flues, is a suitable one for growing pine-apple plants of any size; for by linings of dung the air in it can be kept to a degree of heat sufficient to grow and ripen the pine-apple in summer, as well as it can be done with fire-heat; only it will require a little more labor and plenty of dung." Baldwin, as already observed, grows both his nursery and succession plants in a bark-bed excited by external linings of dung.

2723. Culture of nursing-plants. Whether pits or hot-beds be adopted, the potting, temperature, air, water, &c. are nearly the same.

2724. Potting by Speedly. For full-sized crowns and suckers, Speedly employs pots six inches diameter at top, and five and a half inches deep. Less-sized suckers and crowns, he puts in less-sized pots. He pots ripe or knobby-bottomed suckers immediately after taking off, letting the others lie a few days to harden. He inserts the end of the sucker no farther into the earth than what is necessary to hold the plant fast. They are to remain ten or twelve weeks without water, and afterwards be watered twice a week. (Treat. on the Pine, 35.)

2725. Potting by Abercrombie. "The pots, to receive unstruck crowns and suckers, should be three inches and a quarter in diameter, and four inches and a quarter in height; and the larger the pots, the smaller should be the diameter, and six inches deep, for the larger. Lay at the bottom of each pot dry shivers, or clean gravel, to an inch in depth. Fill the pots with the compost before described, not pressing it too close. With a dibble make a hole, for the smaller plants, two inches deep; and two inches and a half, for the larger. Set the crowns in the hole, and cover them with a little compost; fill up the pot with the rest of the compost, leaving between each an interval equal to the diameter of the pot. After planting, shut the house; and withhold water and admissions of air for some time."

2726. Potting by Griffin. While the fruit is being prepared for unstruck crowns and suckers, towards the end of August or in September, I planted them in rich earth in pots suitable to the size of the plants; I then had the pots plunged to their rims in the tan-bed in which there was a good growing heat; the lights were then shut down close, and as great a heat kept among the plants as could be obtained. Then, when the sun was not so very bright, the plants were shaded a few hours in the middle of the day. The plants were thus managed till they had struck root and begun to grow, when a gentle watering was given to them, and a little air admitted daily. About the end of October, beginning of November, if the state of the bed required it, a little fresh tan was added, and if the plants by the 29th November had not increased considerably, some of them were removed into and, at the same time, the remainder plunged into the tan-bed, in which they continued till February or March, when the pots were thought to require an addition of fresh tan, which was given it, and the plants plunged again into it at this time from the earth in which they had been given to them."

2727. Potting by Nicoll. Twist off a few of the bottom leaves, and pare the end of the stump smooth with the knife. Then pot any pots of about three or four inches diameter, and five or six inches deep, (the less for the larger plants, the larger for the smallest plants,) with very fine, light earth, or with entire vegetable mould of tree-leaves, quite to the brim; placing them, some of them, quite over the other over from each, and serving to lay in the mould loosely. Thrust the larger suckers down to within two inches of the gravel, and the small ones and crowns, two inches in the mould; firming them with the thumbs, and dressing off the mould beneath the nursery-pot, then plunge them into the pots; then when the pots have been plunged into the pots, they may be placed to the clear distance of four or six inches from each other, according to the sizes of the plants, they will have sufficient room to grow till it is time for shifting.

2728. Potting by Griffin and Baldwin. Griffin plants suckers and crowns in pots five inches diameter, and four inches deep; and very strong ones in pots seven and a quarter wide by six and a half deep. Baldwin plants his nursing plants in the bark-bed, without pots.

2729. Temperature of nursing-plants. Speedly does not mention his summer temperature for nursing-plants, farther than referring to a peculiar thermometer which he used, and "made for sale;" but he says, after the beginning of November, "the house should be kept in a cold state, and little or no water given the plants till the middle or latter end of January." (Treat. on the Pine, p. 39.)
2730. **Abercrombie** is more definite: "The artificial heat in the nursing-pit is 55° for the minimum. This will keep the plants, in winter, secured from a check, and a few degrees above a dormant state. It is enough to air at this maximum, when dung-heist is employed; for as its decline is never abrupt, there is no danger in going pretty close to the lowest extreme. When fire-heat is applied, it is better to aim at 60°, as the charge in the flues is more liable to fluctuate suddenly. The maximum artificial heat, in winter, need not go beyond 60°, as the season for excites the advances, this becomes the minimum. When the plants are growing vigorously in the open ground, the artificial maximum is 70°. In winter, the minimum, with the aid of sunshine, should not be allowed to rise higher than 70°, because the benefit of airing would be lost: in summer, the maximum, under the effect of strong sunshine, may rise to 85°; to keep it down, just this amount, give, in July and August, the benefit of air freely."

2731. *M'Phail* says, "The heat of the air in the nursing-pit, exclusive of sun-heat, is not required to be greater than from 60° to 65°. But at first planting of crowns and suckers, he gives them "a great heat and no air till they begin to grow." (Gard. Rem. 81. 319.)

2732. *M'Phail* directs the temperature of the nursing-pit in January with fire-heat, to be kept, as near as possible, to 65°, mornings and evenings; and in sunshine, on good days, it may be allowed to rise about 70°. In March, from 70° to 80°, and after newly potting and plunging unstruck crowns and suckers, to 80° or 85°.

2733. **Covering at nights.** One great advantage of growing pines in pits is, that they may easily be covered with mats, or by other means, in winter. Abercrombie considers covering not positively indispensable to flued pits, in which the minimum degree of fire-heat is regularly maintained; but it will add to the security of the plants, and admit of some retrenchments in fuel, if some warmer screen, in addition to that of the glass, is applied at night, during all the season when frost prevails, or may be expected. For this purpose, provide either double mats, or a strong canvass cover. The latter is commodious, because it can be mounted on rollers, and let down at will, or drawn up under a weather-board. Remove the covering at sunrise, that the essential benefit may not be obstructed.

2734. *M'Phail* covers his pits during the colder months. In January, he "covered up about three or four o'clock in the afternoon, and uncovered in the morning about eight or nine. In very cold weather, it may be necessary, sometimes, not to uncover them in the day-time, only as far as to give them a little light."

2735. *Nicol* says, "The pit should be carefully covered up soon after sunset every evening, either with double mats, or with a proper thick canvass cover, made on purpose for it, and mounted on rollers. The cover should be removed by sunrise in the morning, and should never be kept on through the day, except occasionally, in very severe weather. For if all the light possible be not admitted to the plants, they lose color, and become sickly. By using a proper cover, however, in the night, and only in very severe weather in the day, at particular times, a considerable deal of fuel may be saved."

2736. *Griffith, Baldwin, and Weeks* offer nothing on covering any description of pine frame or pit.

2737. **Air.** When the weather is warm, Speedily admits "a great deal of air" to nurse-plants. Having potted unstruck offsets, Abercrombie admits little or no air until the plants begin to grow; but as soon as the leaves show that the root has struck, he gives plenty of air, in order to make the leaves expand, and the entire plant robust. (Pr. G. p. 628.) "Speaking of the winter treatment of pines, *M'Phail* says, "Admit air in fine days into every place where pine-plants are." In warm summer weather, he admits some all night. (G. Rem. p. 142.)

2738. *Nicol* says, "Air should be admitted to the nursing-pit every good day to a certain extent; dividing the quantity admitted equally, that there may be a regular circulation in all parts of the pit. Even in hard frost, when the sun shines, two or three of the lights should be slipped down, to let the rarefied air escape at top." After potting unrooted offsets, he gives no air till the heat begins to rise in the barn-bed; but *M'Phail* be as warm as the growth in the pit, given in larger portions, especially in sunshine, so as to keep down the thermometer to 65° or 80°. Griffith gives air at all favorable opportunities. Baldwin from the back and ends, but not from the roof, either in summer or winter.

2739. **Watering the nursing-pit.** Speedily waters offsets over the leaves after they have begun to strike, but gives to all pines much less water in a moist than a dry season, depending on the humidity of the air. (Tr. on Pine, p. 37.) He waters once a week or fortnight in September and October, and then leaves off till the middle or end of January, depending on the moisture of the tan, and the state of inaction of the plants. In frosty weather, he sometimes plunges the pots so deep in the tan that their rims may be covered two or three inches in order to give heat, and prevent the surface of the mould from becoming too dry. In March, he waters once in a week or ten days, and advances to twice a week in summer. (Tr. on Pine, p. 47.)

2740. **Abercrombie**, after planting crowns and suckers, gives no water till "the heat of the bark has risen, and the plants show signs of striking. Then water moderately at the root; but give none over the herb until the heart-leaves begin to grow. Meanwhile repeat watering at the root every four days. After the plant is established, water freely at the root, and give sprinklings over the leaves from a fine rose-pan."

2741. *M'Phail* says, "No certain rule can be laid down for the exact quantity of water that must be given to the pine-apple plant, or how often; nor is it necessary to be particular. These and many other matters depend on the care of the plants. In July, it 'begs watering the earth in the pots in which the roots of the plants grow, when it begins to get dry, the leaves and fruit should be watered now and then, till they are all wetted, with clean water out of a fine-rosed pot; the water should be as warm as the sun, and the heat of the air in the house. The best time to water over the leaves, is about eight o'clock in the morning, or about four in the afternoon; though it will do them no harm to water them at any time of the day, if you keep the air in the house sweet, and up to a heat strong enough for the growth of the pine-plant. The plants in this month will want water about once a week, and if the weather be hot, perhaps oftener. However, it is rare that pine-apple plants require water oftener than twice a week."

2742. *Nicol* says, nurse-plants require very little water in winter; "perhaps a little only once in eight
PRACTICE and PART III.

2743. Temperature of the water. M'Phail says, "Eighty degrees is the medium heat of the water with which pines should be watered." He adds, "I would advise never to water them with water under seventy, unless in very warm weather, when the earth about their roots will soon regain its natural warmth." (G. Rem. p. 128.)

2744. Steaming. M'Phail obtains this in summer "by sprinkling the flues and paths now and then with clean water in the afternoon, and shuts up the houses with a strong heat in them." (G. Rem. p. 240.)

2745. Skading. This, the authors quoted, agree in recommending during bright sunshine, after newly potting offsets. Abercrombie says, "shade them with thin mats in the middle of hot days; dividing the hours before and after twelve, so as to amount to a fourth of the morning, and a third of the afternoon." (Pr. G. p. 639.) Speechly approves of skading, and effects it in an ornamental and useful manner by training vines on the rafters.

2746. Shifting nurse-plants. "Offsets planted early in the season," Speechly says, "should be carefully looked over in September, and all the forward crowns and suckers that are grown large, and with an appearance of being under-potted, should be removed into larger-sized pots, with their roots and bulbs entire." (Tr. on Pine, p. 38.)

2747. Abercrombie says, "When offsets have been potted in July or August, remember to observe the roots of the most vigorous plants. Should any have filled the pots, shift them into larger; but new roots will not often have filled the pots at that inconvenient period." (Pr. G. p. 638.)

2748. M'Phail does not shift unstruck crowns and suckers, planted in the end of August or September, till the following March or April, and pots with entire balls like Nicol.

2749. Nicol new-pots offsets planted in summer in the following March. "Let them be shaken out entirely, and with the large-sized sea-gravel, and then be turned to their pots, and let them be replaced in the same, or in similar pots. The proper size of pots, however, in which to put crowns and suckers struck last season, is about four inches inside diameter at top, and six inches deep. A little clean gravel should be laid at the bottom of each pot, in order to drain off extra moisture, and this should be observed in the potting of pine-plants of all sorts. I have generally observed, that if the bark-heat be not violent, the plants will push very strong fibres into this stratum of gravel, in which they seem to delight. I therefore generally make it two inches thick in small pots, and three or four in larger ones, less or more, according to their sizes. From the time I first adopted this mode of potting, I hardly ever had an instance of an unhealthy plant; and this very particular, together with that of keeping the plants always in a mild bottom heat, is of greater importance in the culture of pines, than all the other rules is been having respect them, out of the ordinary way. The roots of pines seem to delight in gravel; and I have been careful to introduce it into the mould for plants of all sorts. I generally used small sea-gravel, in which was a considerable proportion of shells, or chips of shells, with other particles of a porous nature; and I have uniformly observed the finest fibres cling to these, and often insinuate themselves through the more or less earthy embrace of the gravel. A little sea-gravel can be obtained, prefer it; and next, river-gravel; but avoid earthy pit-gravel, and rather use sharp sand, or a mixture of pounded stones, chips, and brick-bats. The plants being repotted, plunge them in the bark-bed again, quite down to the rims of the pots, keeping them perfectly level. Eight or nine inches from centre to centre will be distance sufficient. When they are all placed, give a little aired water, to settle the earth about their roots. This need not be repeated till the heat in the bed rise to the pots, after which, as the plants will now begin to grow freely, they must be watered at the root once in four or five days; and they may have a drowsing over head, from the fine rose of a watering-pot, occasional lately, if the weather be fine."  

2750. In May, Nicol again shifts, "but the plants are not to be shaken out at this time, but are to be shifted, balls entire, into pots of about six inches diameter, and eight inches deep. If the roots be any- wise matted at bottom, or at the sides, they must be carefully singled out; and in potting, be sure that there be no cavity left between the ball and the sides of the new pot. In order the more effectually to prevent which, use a small, blunt-pointed, somewhat wedge-shaped stick, to trimle in the mould with; let the pots be in a dry state; and be sifted fine; and also to shake the pot well (potting on a bench or table), the better to settle the earth about the ball. Pots of this size should be filled to two inches of the rims (the ball being covered about an inch with fresh earth), as the whole will settle about as much, and so leave a full inch for holding water, which is enough. In preparing the plants for potting, observe to twist off a few of the bottom leaves, as they all put out fine roots from the lower part of the stem. Also, before letting the potting out of hand, trim off the points of any leaves that may have been bruised or anywise injured in the shifting. Replace the pots to the brim, as before, observing to keep them to a limit, at the distance of fifteen inches from centre to centre of the plants on a medium; then, with a little water, which need not be repeated, water with the bottom.  

2751. Nicol, in November, shifts such others whose roots have filled their pots, and have become any- wise matted. "Examine any you suspect to be so, and let them be shifted into pots of the next size im- mediately; if they are in quantity or being in the heaviest pots, may require an extra quantity of air purposely admitted. This precaution, however, is only necessary for the sake of such crowns and suckers as have been struck late last season, and are not very well rooted; such being more apt to drop off than others that are better established." In summer he supplies water regularly and plentifully, and in winter he allows the waterer to stand in the pots, and shallow it weekly, or rather every second week, according to the quantity of air purposely admitted. Water frequently with the draining of the dung-hill.

2752. Insects and diseases. See this article under General Directions. (Subsect. 8.)
Subsect. 6. Succession Department.

2753. The culture of succession pine-plants necessarily coincides in many particulars with that of nurseries; but less heat is generally allowed the former in order not to draw them; and they are allowed plenty of room in the bed, frequently shifted, and abundance of air admitted, in order to make them broad-bottomed and bushy: thus strengthening the heart or root part, in order that it may throw up a strong fruit the second or third year.

2754. Growing succession plants without fire-heat. M'Phail says, "Succession pine-plants grow exceedingly well in pits covered with glazed frames, linings of warm dung being applied to them in cold frosty weather. The north wall of a pit for this purpose had best be only about four feet above the ground; and if about two feet high of it, the whole length of the wall, beginning just at the surface of the ground four feet below the height of the wall, be built in the form of the outside walls of my cucumber bed, the lining will warm the air in the pit more easily than if the wall were built solid. The linings of dung should not be lower in their foundation than the surface of the tan in the pits in which the plants grow (for it is not the tan that requires to be warmed, but the air among the plants); and as during the winter the heat of the air in the pit among the plants, exclusive of sun-heat, is not required to be greater than from sixty to sixty-five degrees, strong linings are not wanted: one against the north side, kept up in cold weather nearly as high as the wall, will be sufficient, unless the weather get very cold indeed, in which case a lining on the south side may be applied. In cold, frosty weather, a covering of hay or straw, or of fern, can be laid on the glass above mats in the night-time."

2755. Most nurserymen and growers of plants for the London market employ dung-beds of the common kind, keeping up the heat by powerful linings. The same practice is successfully adopted by Miller and Sweet, of Bristol. Baldwin combines the nursing and succession beds, growing both on tan with dung-linings.

2756. Shifting and potting. The middle of March Speechly considers the most eligible time for shifting and potting such nurse-plants as are to be removed to the succession-house. "If the work is done sooner," he says, "it will prevent the plants from striking freely; and if deferred longer, it will check them in their summer growth."—In this shifting, he "always shakes off the whole of the ball of earth, and cuts off all the roots that are of a black color, carefully preserving such only as are white and strong. He then puts the plants into pots eight inches and a half diameter at the top, and seven inches deep, in entirely fresh mould. The bark-bed is renewed, the pots plunged to the rims, the house is kept pretty warm, till the heat of the tan arises; the plants are then sprinkled over the leaves with water, and watered first once a week and afterwards twice a week, till next shifting in the beginning of August, when they are shifted into fruiting-pots with their balls entire. The size of these pots is eleven inches and a half at top by ten inches deep."

2757. Abercrombie observes, that most of the remarks on the nursing-house will apply to the succession-pit. "Sometimes the plants, originated in the nursing-pit in August or September, will be fit to bring into the succession-house in March or April following; and sometimes not till the anniversary season. Those from late fruiters, originated in March, will be most established by the end of summer."

2758. Introductory shifting. Where at the first shifting of rooted plants, they are transferred to this department, proceed as in nursing-pit, except in regard to the size of the pots, which should be twenty-four inches, or about seven inches across, and nine deep. When the plants are a year old, and the shifting for culture here is the second or third, begin as before: — make arrangements to complete the business in one day. Be prepared with a bed of lively tan, the number of pots, the compost for pines, and some clean sea-gravel or shivers. As each plant is taken from the nursing-pit, tie the leaves together. Turn them out of the old pots singly. Then proceed as follows: — Shake off the ball of mould. Strip off a few of the lower leaves. Cut the roots off entirely: further, if the roots are scanty, or decaying, prune away a small portion of the stem, cutting into the quick. Pot the plants: plunge them in the tan, not entirely to their rims, till the new heat rising from the bark can be ascertained. Leave about five inches space between each. Keep them under a strong heat; and forbear to give water, or to admit cold air, till the plants have struck root.

2759. Intermediate shifting. When plants are to remain in the succession-house a year, shift them in the March following their introduction. Let the fresh pots be full eight inches in diameter, and ten inches deep. It is one of the most availing precautions against the premature fruiting of pines, to allow rising plants a capacious bed, and free space for the herb to expand. In turning healthy plants, now, out of the old pots, endeavor to preserve the ball of earth entire. But where plants appear to be sickly, to be infested with insects, or to have bad roots, brush away the old earth entirely: then with a long knife trim the longest fibres; and if any part of the main root be unsound,
cut it away. Strip off some of the lower leaves. Replant in the new pots. Set the plants in the bark-bed, leaving the pots partly out, lest the first heat should be too strong. There should be a distance of seven inches from pot to pot. Water full-rooted plants gently, to settle the mould. Plants divested of roots are not at present to receive water.

2760. Second intermediate shifting. The roots of large plants which were shifted in March should be examined at the end of May, or in June. If they have filled the pots, it will be necessary to shift them into pots of an increased size, so as to admit new compost to the extent of an inch all round the old ball. The diameter of the crate at top should be nine inches; the depth twelve, including an inch of pearly gravel at the bottom. If the roots are matted, carefully disentangle them: prune off old fibres, or not, according as the root has been spared or retrenched. In all cases, cut away unsoaked parts of the root, and slip off a few of the oldest leaves. After replanting, distribute the pots eight inches apart over the surface of the bed, without plunging them to their full depth, till the heat of the renewed tan is ascertained.

2761. M'Pail says, "If in March you have any nurse-pines a year old, shift and repot them at this season. Having a bed prepared for them, strong enough to raise a good heat, take the plants and tie their leaves tightly together; then turn them out over after another day, or all their roots close on the stem; and if the stems of them be bare of roots, or appear rotting or black, cut a part of them off up to the quick. Rub the mould clean from the stems, divest them of a few of the lower leaves, and pot them in good rich mould, in small pots suitable to the size of the plants, and plunge them in the tan up to their roots. If the pots have been done over or renewed, fill them with earth, and if there be then no air nor water till they have struck root and begin to grow; but remember, the earth should be moist in which they are potted, for no plants can make shoots without moisture. When large succession plants have been divested of their roots, and potted in the mouth of March, they will probably by this time have made their shoots, so that they be well enough to admit of muff falling easily round their tail. If they were not shifted when the roots begin to get matted, it would check them, and probably make them fruit in August or September. In August or September, the plants are again shifted into pots large enough to admit earth easily round their balls between the plants and the sides of the pots." In these pots, let the plants remain in general till the fruit is over. (Gard. Rem. 82.)

2762. M'Pail and Speedy agree in remarking, that "some large kinds of pine-apple plants require three seasons to grow before they can bring large-sized fruit, such as the black Antigua, the Jamsies, the Ripley, &c.; therefore, in the month of April or May, after they have been planted upwards of a year, it is best to take them out of the pots, and to cut off all their roots close to the stem, or leave only a few which are fresh and strong, and then plant them again in good earth in clean pots, and plunge the pots in a barrel of the tan, or a scuttle in it. As a shift of plants is the best procuring fresh roots, so, till the plants have made fresh roots and their leaves be perceived to grow, when a little water may be given to them, which, together with a good bottom and top heat, will make them grow finely." (Gard. Rem. 83.)

2763. Neil recommends a general potting of the succession plants in August, when the fruit are all or nearly all cut; removing the old stock's from which the fruit had been cut to make room for them in the fruiting-pit. "The nurse-plants now become the succession; the succession the fruiters for next season, and the crowns and suckers produced by the plants whose fruit have been cut, occupy the nursing-pit." (Kot. 410.)

The succession plants, before removal into the fruiting-pit, must be shifted into pots of about eleven or twelve inches diameter, and fourteen or fifteen inches deep. The plants should be plunged entirely in old tan to within an inch or two of their brims, keeping them quite level, and eighteen or twenty inches centre from centre. Great care must be taken to keep the heat of the bark-bed moderate and steady, lest the plants should start into fruit, which, if they did, they would next be lost. I would rather have a one-year-old than a two-year-old plant show now, as the loss would evidently be less; but frequently the former will bring a better fruit than the latter in the end of the season. Some of the succession, potted from the nurse-pit in August, may require repotting in November; but, in general, not till March, when the plants are to be shaken out of their pots, and replaced in the same or similar pots (seven or eight inches diameter, by nine or ten deep) in fresh mould, placing some gravel at bottom. The plants are then to be replugged (the bark-bed being refreshed, &c. agreeably to the general mode of management) laid down in Succession. To keep the distance fifteen inches from each other. In this state they remain till May, when they are reshifted with their balls into pots a size larger (nine or ten inches diameter, and twelve deep), and plunged till August, when they are shifted into fruiting-pots (eleven or twelve inches diameter, and fourteen or fifteen deep) and removed to the fruiting-pit as above described. (Kot. 413.)

2764. Griffin shifts his succession plants for the second time, in March, into pots nine inches in diameter, by eight inches deep, "turning each singly out of its present pot, with the ball of earth entirely shaken off, and plunging them as healthy or any ways defective, when it is eligible to shake the earth from the roots, and trim off all the parts that appear not alive. He plunges them in the bark (refreshed as at each shifting) eighteen inches from plant to plant in the row, and twenty inches' distance row from row.

It is to be observed here, that Griffin's practice, in not divesting the plants entirely of their balls at each shifting, and not shaking them with brims off, but directly into the pots, Griffin, as it is alleged, obtains larger fruit; and Baldwin, by his practice, fruits the plants a year sooner, that is, in fifteen and eighteen months.

The practice is to make up the crowns and suckers planted in the tan in September in the succeeding April; divest them of all their roots, which "must not," he says, "be taken off at any future transplanting," and put into pots of five, six, or seven inches' diameter, according to the size of the plant. About the middle of the following June, when the pots are beginning to be filled with roots, take out the plants with the root, and cut away the earth from them in the pots, put nine inches' distance between them in the pot; replunge them into your bed, and let them remain till the end of September. (Cott. of Anan. p. 15.)

2765. The practice of shaking off the balls of earth, and cutting off the lower roots of pine in the second year's spring shifting, has at first sight an unnatural appearance, and various theorists, and some gardeners, recommend shifting the plants from first to last with their balls entire. On attentively examining the pine-plant, however, it will be found, that, in its mode of rooting, it may be classed with the strawberry, vine, and crowfoot, which throw out fresh roots every year, in part among, but chiefly above the old ones. This done, the old ones become torpid and decay, and to cut them clear away, if it could be done in all plants of this habit, would no doubt be assisting nature, and contribute to the
growth of the new roofs. At the same time, it is to be observed, that encouraging, in an extraordinary degree, the production of roots, though it will ultimately increase the vigor of the herb and fruit, will retard their progress.

2767. On shifting with the balls entire. Speckly has the following judicious observations, which coincide with those we have above submitted:

2768. First. It is observable, that the pine-plant begins to make its roots at the very bottom of the stem, and as the plant increases in size, fresh roots are produced from the stem, still higher and higher; and the bottom roots die in proportion: so that, if a plant in the greatest vigor be turned out of its pot as soon as the fruit is cut, there will be found at the bottom a part of the stem, several inches in length, naked of roots, and smooth; now, according to the above method, the whole of the roots, which the plant produces being permitted to remain on the stem to the last, the old roots decay and turn mouldy, to the great detriment of those afterwards produced. Secondly, The first ball which remains with the plant full two years, by length of time will become hard, shrivelled, and exhausted of its nutrition; and the fresh roots afterwards produced from growing with that freedom and vigor, which they would do in fresher and better mould. Thirdly, The old ball continually remaining after the frequent shifting, it will be too large when put into the fruiting-pot, to admit of a sufficient quantity of fresh mould to support the plant till its fruit becomes ripe, which is generally a whole year from the last time of shifting.

2769. Temperature. Speckly approves of rather a lower top and bottom heat for pines in the winter season than what some later authors recommend. "There is nothing so prejudicial to the pine-apple plant, (insects and an overheat of the tan excepted,) as forcing them to grow by making large fires, and keeping the hot-house warm at an improper season, which is injudiciously done in many hot-houses. It is inconsistent with reason, and against nature, to force a tropical plant in this climate in a cold, dark season, such as generally happens here in the months of November and December; and plants so treated, will in time show the injury done them; if large plants for fruiting, they generally show very small fruit-buds with weak stems; and, if small plants, they seldom make much progress in the beginning of the next summer." "In the hot regions," Abercromble observes, "to which the pine-apple is indigenous, the growth of the herb and fruit proceeds, at all times of the year, as the new plant may happen to spring, and as the advancement of the herb, and the expansion of the organs of fructification follow at natural intervals. Thus the rising and intermediate pines have, at home, the same heat as fruiting plants. As the force of the climate is always equal to conduct the plant to the next stage, whatever the present may be, nature's plants always show their blossoms opportunely; and the fruit is swelled to perfection, however different periods of growth in plants of one family fall together. But, under a course of artificial culture, although a similar promptaneous succession may go on, and be cherished to the end of fruiting without miscarriage; yet to let the critical periods of growth fall in winter, without any failure of the crop, or deabusement of the fruit, requires so much additional expense and attendance, that our cultivators of pines endeavour to keep the main stock of established plants just vegetating in winter, and to bring the time of full expansion in the herb, and as much as may be of the long and trying time of fructification, to coincide with the spring and summer of this climate. The dependence of the plant on artificial excitement is then so much less. Hence, though it is contrary to the free progress of nature, the successions pines are kept under a temperature rather lower than that of the nursing-pit, in order that while the complete development of the herb is provided for, the plant may not be excited into fruit prematurely in regard to its age, nor unseasonably as to the course of the natural climate during the period which the fruit will take to ripen."

2770. The minimum temperature for succession plants, on which the preservation of a gentle course of growth depends, cannot be safely reduced lower than that which is specified under Temperature in Nursing Department. But it is important to carry the maximum, as it respects both fire-heats, and the accumulation of sun-heat in the chamber, no higher in this than is fixed for that department, and rather to aim at a maximum from two to five degrees less intense. Thus the double object, of avoiding to excite the plants too strongly, and of giving air at a good opportunity, will be consulted. (See the Table.)

2771. M'Phail says, "Let the succession-plant pines have about the same degree of heat to their roots in the tan-bed, and in the air of the house about them, as I have recommended for the fruiting plants; viz. from 80 to 100 at the bottom of the pots, and from 65 to 80 in the atmosphere of the house. Some writers," he says, "recommend a lower heat for the fruiting plants; but I have been of another opinion. I can see no reason for making the difference, nor did I make a practice of doing it, except to young plants in winter, in pits without fire-heat, which at that season could not be done in the same degree which might have been done by the influence of the fire. When succession plants are kept in a less degree of heat than that necessary for fruiting them, they require a longer time to bring them to a proper size for producing large fruit; and of course the expense of rearing them is greater than when they are kept in a vigorous growing state. Nothing better suits a pine-apple, nor any fruit-bearing plant, than to keep it in a vigorous growing state, from the time it is planted till it ripens its fruit." (Gard. Rev. 192.)

2772. M'Phail says, "The temperature in January by fire-heat should be kept as near to 60° as possible, and even in sunshine, should not be allowed to pass 65°, lest the plants start into fruit." In May, he in-
ceases the heat to between 65° and 70° in the night. In August, he keeps down the thermometer to 75° or 80° in the day-time. In September, he returns to 65° in the night, and 70° or 75° with air in the day. In October, he descends to 60° mornings and evenings, and 65° in sunshine.

2773. Griffin differs from the above authors in recommending 60° as the heat proper for the pine in every stage, not exceeding five or six degrees over or under. The bottom heat he considers proper, is from 90 to 100 degrees! (Tr. on the Pine, p. 60, 66.)

2774. Baldwin does not mention at what temperature he keeps his succession-pit.

2775. Covering at nights. Where succession plants are grown in pits or frames, this is allowed on all hands to be most advantageous, by saving fuel, and preventing the risk of an injurious cooling, which in pits and houses warmed by fire, and unprotected but by the glass, will sometimes happen under the best management. Practical men recommend mats, canvass, litter, &c. laid on the frames; but a great improvement consists in keeping the covering of whatever nature, and especially if of mats or canvass, at not less than six inches on the principle experimentally illustrated by Dr. Wells in his Essay on Dew; Leslie, in his experiments on concentric cases (Essay on Hout), and derivable from the fact known to scientific men (See Young's Lect.), that heat follows the same general laws as light.

2776. Speedy and Nicol complain of the great breakupage of glass, by covering with mats, litter, &c.

2777. Seton adopts portable covers of straw, arranged in the manner of thatch, and which may be compared to the panels of wicker fences or screens. They are formed on four laths, fixed at the same width as the pit or frame one way, and not more than four feet apart the other. The chief advantage is, that the water runs off the thatch, the interior remains perfectly dry, so that there is no consumption of heat by the creation of vapor in those parts which are near the glass; "whereas mats, cloth, loose straw, and other similar coverings become impregnated with moisture every night from dew, rain, or snow, and the evaporation which is thereby constantly generated, and greatly augmented by the contact of the warm glass, causes a vast and continued drain of heat." Another advantage is the facility with which they may be put on and taken off, and the little risk there is of breaking glass during these operations. (Hort. Trans. iii. 290.)

2778. Air. Speedy considers a due proportion of air as essential to the goodness of pine-plants. The want of it will cause them to grow with long leaves and weak stems; and too great a quantity, or air given at improper seasons, will starve the plants, and cause them to grow yellow and sickly. Little air will be wanted in winter; but letting down the glasses, even for a few minutes in the middle of the day, should never be neglected in fine weather, to let out the foul air. This will cause the plants to grow with broad leaves, and stiff and strong stems, provided they have room in the bed. Air may be admitted all night in the hot season, care being taking that the glasses are left in such a manner as to prevent the rain, in case any falls, from coming on the plants. (Tr. on the Pine, p. 75.)

2779. Abercrombie gives abundance of air in July and August, but with due caution the rest of the year.

2780. McPhail admits more or less air every fine day during spring and autumn, and abundance in the summer months, which is also the practice of Nicol, Griffin, and Weeks. Baldwin seems to admit air rather more sparingly than these gardeners.

2781. Water. Speedy disapproves of ever giving a great quantity of water at one time to the pine-apple plant, in any stage or at any season. Too much causes the mould in the pot to run together and become hard and cloddy; and, independently of this, glutting a plant with water will rob it of its vigor, and reduce it to a weak state. Hence, though keeping of plants too dry is certainly an error, it is not attended with the same fatal consequences as the contrary practice. Watering the walks and flues, &c. in an evening, in order to raise a kind of artificial dew, is in imitation of what takes place in the West Indies, where no rain falls in the summer for many months together, and the plants are wholly supplied with moisture from the dew. Gentle summer waterings over the top are founded on this principle. "Plants lately shifted into the pots, till their roots get matted, do not require so much water as before their shifting. Plants that are in large-sized pots, in proportion to the size of the plants, do not require so much water as plants that are under-potted. Plants that are in hard-burnt pots, made of strong clay, do not require near so much water as plants in pots less burnt, and made of clay with a good proportion of sand intermixed. The latter are greatly to be preferred. Plants in a vigorous growing state require very frequent and gentle waterings. But plants with fruit and suckers upon them require most of all. When plants are watered over their leaves, it should be sprinkled upon them only till every part is made wet, which may easily be distinguished, as the water immediately changes the color of them to a sad green. As the leaves stand in different directions, the best method is to dash the water upon them backwards and forwards, on every side of the bed. Summer waterings should always be given late in an evening; but in the spring and autumn, the forenoon is the proper time. Less water should be given in moist than in dry weather, for reasons already given. In winter, when water by accident falls into the centres of the fruiting plants, it should immediately be drawn out, which may easily be effected by the help of a tin pipe of about three feet in length, one end of which should be no bigger than the small end of a tobacco-pipe." Pond or river water, or water collected from the roof of the hot-house, and retained within the house till it has attained its temperature, is to be preferred. (Tr. on the Pine, 81, 82.)
Pinery. — FRUITING DEPARTMENT.

2782. Abercrombie, from March to September, gives most water, "keeping the mould during this season constantly a little moist." In the other months he diminishes the quantity according to the season and circumstances of the temperature, plants, &c. He uses soft water at 75°, and gives it through a tube composed of potted pieces, so that it may be shortened at will, to prevent its falling into the hearts of the plants. He also steams the flues occasionally, and waters with drainings of the dung-hill in the growing season. (Pr. G. 627, 628.)

2783. M'Phail says, "Of two evils, it is better to give pine-plants too little water than too much." He gives little in the winter months, but more freely in summer. He sprinkles the leaves occasionally with clean water, not less than 70 degrees warm, and shuts them down in the afternoon with a strong heat in the house. He judges of the temperature of the water by taking a mouthful of it; and if it feel neither hot nor cold, he is in a good state, being upwards of 85 degrees. (Gard. Rem. 220.) When you water your pines, recollect that some sorts require less water than others; the sorts called the queen and the sugar-loaf require rather more water than those called Antigua, black Jamaica, and some others of the large-growing sorts. In July succession pines require frequent waterings. It is a good sign to see plants growing through, and the water standing constantly in their hearts, as well as on their foliage. It is plain, therefore, that dampness: is of the utmost importance in pining, especially during the winter season. (G. 2786.)

2784. The growth of the plants is in great measure governed by the amount of water they receive. It should, however, be borne in mind that the watering of pines is not so important as the ventilation of the houses. What is the cause of the pines not growing as well in a house stocked with species as in a house where the space is proportionately smaller? The difference, says M. Denys, is attributed to the want of sufficient ventilation. There is always a partial deficiency of oxygen in the atmosphere of a house. If frequent waterings are required by one species, frequent waterings are also required by others. The waterings are to be with the utmost care and regularity, as it is not intended to force the plants into much growth, it being supposed that they are now very healthy and strong. In October he lessens and retracts the waterings, and during winter waters very moderately once in four, five, or six days; but at the root only. (Kal. 462.)

2785. Griffin waters moderately in winter, and more liberally in the growing season, from March till October, and want of water to keep the plants moist being one of the reasons of their premature fruiting. Griffin says, "I have planted from five to twenty trees in the same part of the green-room, and watered them all alike, but after potting, waters two or three times a week during the summer, according as the temperature may be.

2787. Shading. "Succession pine-plants," Speechly observes, "do not make half the progress in violent hot weather in the middle of summer, that they do later in the season. In order to obviate the above inconveniences, some persons cover their hot-houses in the middle of the day, when the heat of the sun is violent, with bass mats fastened to a rope, which may be moved up and down with great ease. But a better mode, and which is frequently practised, is, to cover the glasses with a large net, which admits the air to pass freely, and at the same time breaks the rays of the sun, and retards their force, especially if the meshes of the net be not large. But if vines were judiciously trained to the rafters of the hot-house, there would be no need of either of the last-mentioned coverings. The vines should be planted in the front of the hot-house, and not more than one shoot trained to each rafter, part of which should be cut down to the bottom of the rafters every season, by which means the roof of the hot-house may constantly be kept thinly covered with young wood, and by having only one shoot to each rafter, the vine-leaves will afford a kindly shade, and never incommodate the pines; for the leaves fall, and the vines are pruned at a season when the hot-house most requires sun."

2788. Abercrombie only shades new-potted plants till they have struck root. He uses thin mats as in the nursing-pit. (Pr. Gr. 628.)

2789. M'Phail uses no screens or covers for shades, but supposes his succession plants grown houses in which vines are trained under the rafters.

2790. Dressing the plants, &c. Most of the authors quoted agree in recommending decayed or casually bruised leaves to be twisted off, if they are at the bottom of the stem; or such as grow on it carefully trimmed off with the knife. In the season of free excited growth, Abercrombie says, "Midway between the times of shifting, take off about two inches of the upper mould, and replace it by fresh compost." Remove all fungi which grow out of the tan, and in general keep every part of the pinery at all times clean and sweet.

2791. Insects and Diseases. See General Directions. (Subsect. 8.)

SUBSECT. 7. FRUITING DEPARTMENT.

2792. The culture of the fruiting department embraces much of the culture of the nursing and succession pits: but little difference, for example, is made in temperature, air, and watering, till the last stage of the maturation of the fruit.

2793. Abercrombie observes "that the pine-apple can be carried even through the last stage without fireheat: but the fruiting-house is a department in which the aid of the furnace should least of all be relinquished, unless some very great facilities for employing dung-heat, or some obstacles to the working of a stove, attend the situation. The pine-apple is a large, long-branching plant, requiring a large degree of heat and ventilation. These, from their always being kept up to a high degree of heat, are by gardeners usually termed roasters. When there is such convenience, it is customary, when any pine-plants show fruit in the large stores (as they do occasionally), to put them in the fruiting-house; where, from the high degree of heat kept, they generally swell their fruit astonishingly."

2794. Griffin's house corresponds nearly with the roaster or small house of Speechly; but Baldwin's seems
an improvement, as being much smaller, losing less room in paths, and being comparatively easily heated.

2796. **Shifting and potting.** Speakilly shifts into fruiting-pots in August (see this article under Succession Department), and afterwards, in the following March, divests the plants of a few of their bottom leaves, renews the mould on the tops of the pots as deep as can be done without injuring the roots, and fills up with fresh cow compost earth. He says, “It is very injurious to the plants, and greatly retards the swelling of the fruit to remove them after this season.” (*Ty. on Pine, p. 49.*)

2797. **Abcrombie** differs from this author, in shifting in the spring after the plants show fruit; he says, “The main set of plants from the succession-pit will usually be ready for the fruiting-house in the course of the year, and will be chosen for filling full-grown pots, to be ready for fruiting in the next pot, so as to turn out whole. Late plants may not be in this state till October. The bark-bed, here, must be renewed, as on every occasion of repotting plants: but to guard against an untimely show of fruit, the strength of the new bark must be kept considerably below the extreme limit, and there should be the layer of old bark to the full depth of the pots. For the large sorts, put two inches in diameter and fifteen inches in depth. For forward plants also, which you are apprehensive require free space for the root and herb, to prevent them from fruiting too early, provide pots two inches wider and three inches deeper than those of which they are out to be turned; but the additional room in the pots is not more than you may require to, as the roots will fill up the time at which you propose to take them fruit. On the other hand, if you have any reluctant fruiters, when you transfer them to the fruiting-house, postpone shifting them into new pots, in order that the impalement of the pot by the roots may accelerate their fruiting; or shift them into pots barely large enough to receive the roots, putting them into mould rendered, by an increased quantity of river-sand and fresh loam, somewhat less rich than the compost for pines in general: whichever of these courses may have been taken, as soon as they show fruit in the spring, shift them into large pots, without disturbing the ball of earth; and then fill the pots to the best of your means, Lay in the first food at the same thickness as the thickness of two inches, and as much compost as will keep the ball, or root, to be received, level at top with the rim. At the shifting of plants that come from the succession-pit, twist off some of the leaves, as the ripe sbrs show; the pots, if ready for them, are filled to the rim with the ball of earth entire; set it in the new pot, fill the vacancy with compost, and raise the mould to the lowest leaves by spreading compost over the ball; leaving a hollow descent to the depth of the rim to hold water. Plunge the pots in the tan-bed, distributing those in the same range eight inches apart.”

2798. **Second shifting.** “There is in general no second shifting; but the plants remain in the pots assigned at their coming from the succession-pit till the fruit is ripened. But, 1. In the case mentioned above, there is sometimes a spring shifting. 2. When plants which were regularly shifted, come into fruit early, and it is wished to retard them, you may give them a second shifting in February, or at any time before the fruit has attained half the full diameter; putting them into pots one size larger, and proceeding, in other respects, as at the introductory shifting. Though this acts as a temporary check, the advantage of fresh mould contributes to swell the fruit. 3. To plants which are sickly, or growing out of shape, the best remedy is, to shift them as soon as this is perceived, changing the mould, and pruning away decayed parts of the roots as they may occasion.” (*Abcrombie.*)

2799. **M’Phail,** with Speedchly, shifts finally in August or September; gives a dressing in March, and, in general, does not move them again till they have ripened their fruit, unless to give more bottom heat. Speedchly says, plants increasing in size, as fruiting takes place, the shifting of the smaller pots which their roots do not fill well before the month of January, do not show fruit till late in the spring or summer months. For this reason it is advisable, when they cannot be shifted early enough in the month of August or beginning of September, so as to fill the pots with roots before the winter come on, to put in the pots, after the plants have been shifted till the fruit appears, and the stern of it be grown to its full height, and then shift the plants into larger pots, in the manner before directed, disturbing the roots of the plants as little as can be helped. After the plants are shifted, they must not get much water till the fresh growth of the roots has somewhat exhausted the moisture of the fresh earth put round them. (*Gard. Rem.*)

2800. **Nicoll** shifts finally in August, and top-dresses in February; but plants that are unhealthy, feebly, and do not stand firm in their pots, should be shaken out entirely, and be replaced in the same pots; trimming their roots according as they may need, but retaining all fresh healthy fibres. Any plants that have already started into fruit, should also be shaken out, and be fresh potted, as above; which, by the check they receive, will keep them back to a better season of ripening, and by the force of fresh earth, make them swell their fruit larger than they otherwise would have done. I have thus new-potted plants, ever since I have, with very much success, and have swelled the fruit to a size far beyond my expectations, which may be due in some measure to the action of carbolic acid, of which fact any one may easily satisfy himself, by fresh-potting a few plants, and comparing their progress with others treated in the ordinary way. Let the plants be replunged to the brim as before, keep them for a while full of water, and then allow them to be fully dry. The plants are then to be placed, twenty inches apart from centre to centre, on a medium. But they should be sorted; the smallest placed in front, and the largest at back, as in arranging plants on a stage, they may have an equal share of sun and light. As soon as replaced in the bark-bed, let them have a little water, to settle the earth about their roots. In May he again top-dresses, “reducing an inch or two of the earth from off the surface, and adding some fresh mould, which will invigorate the plants, cause them to push out surface radicles, and so keep them the more firm and steady. This need not be done, however, to plants which have not ripened their fruit; but when the plant is in flower, past the flower, or with the fruit about half grown. And with respect to any that are unhealthy, and whose fruit are less than half grown, do not hesitate to shift them, shaking them out, trimming their roots, and retaining only healthy fibres. This is a very great improvement in the culture of pines, which I formerly practised, having been much advised, and have seen fruit much much improved in this way.”

2801. **Griffins,** shifts, for the last time, in October, with the balls entire as before, allowing them in the bark-bed about twenty inches from plant to plant, and two feet distance from row to row; “the first row eight feet from the kirk, and angling them in rows as you go on.” The pots he uses are twelve inches diameter, and ten inches deep.

2802. **Baldwin** shifts the last time, in September, into pots “of about fourteen inches diameter, at the top,” at first half plunging the pots till the heat diminishes to a safe temperature. He afterwards fills up the interstices with tan, and leaves the plants remain until they are fruited, off for the table. (*Coll. of Amur,* p. 17.)
2803. Temperature. Speechly is not definite on this subject; but observes generally that nothing is so prejudicial to fruiting plants as making the air cold to force them to grow in the winter season; the fruit-buds they send up are small, and the stems weak. "(Try. on Pine, p. 41.)

2804. Air-borneomic observes, "As long as it would be dangerous, or it is not to be expected that the plants will show fruit, the temperature should be kept reduced to that of the succession-pit. But a capital elevation, in the course of heat maintained here, must be made for about eight of the last months, so that the plants will remain in the house, that is, just as it becomes fit to excite them into fruit, and during the whole period of fructification. In the annexed Table, it will be shown, that August, September, October, November, December, and January, should be as low in the first, against the first series of these months is marked the temperature at which it is proper to aim, when the plants have been removed from the succession-pit, in the July preceding, or the current August or September, in order that they may not start into fruit at the beginning or middle of winter. Contraated with this, the second series ris es to the nature of the house; plants which have been removed from the succession-house some months, and in which the object of culture is nearly heat, as that described; but he asserts, that season proceeds, a high course of heat must be continued, to ripen the fruit on these. As to the maximum of artificial heat for plants already in fruit, the degrees are merely to indicate, that it would be an unnecessary expense to go higher; but should the natural climate not supply a greater heat, to go five or ten degrees higher, so far from being attended with danger, would be beneficial to ripening pines, particularly if a high course be given of air and humidity. The maximum in the last column is chiefly to be observed for the sake of fresh air, which will do more good and service the plants, if the fruit will not swell off fine, if the heat from the flues be too languid to support the prescribed minimum temperature, until the full domination of summer supersede the aid of the furnace altogether."

2805. M'Phail has given tables of the temperature in his hot-house, or fruiting-house, for every day in the year, from which we annex the accompanying monthly average. In January the thermometer stood from 63 to 66 degrees in the morning; from 65 to 68 degrees in the middle, and from 68 to 72 in the evening, and so on. On the tables from which the above is extracted, M'Phail observes, " that the thermometer was hung in the middle of the house, out of the direct rays of the sun." He does not offer these tables as exact rules to be followed; nor deny that the pine-apple can be ripened in a different degree of heat; as to which, I have already expressed in my communication. He says, that with heat and management as he recommends will bring the pine-apple to good maturity. "Had I kept a register of the thermometer another year, and compared it with the observations kept for me herein given, there would have been a difference; the heat of every day, week, or year, would not have been alike; nor to cultivate the pine-apple, or any other plant, is it necessary that it should be so."

2806. He observes, "Temp. at the same temperature as the succession department, from 60° to 65°, lest the plants should start into fruit. In February, he requires a "lively, but not violent bottom heat, in order to start the plants into fruit;" the temperature of the air he raised gradually to 70°, not allowing the thermometer to pass 80°. From 72° to 75° is his temperature for March and April. In May, June, July, and August, he requires 72° morning and evenings, and 80° or 85° at noon. In September, after fire-heat becomes necessary, he keeps as nearly as 65° as possible, and in sunshine, by the free admission of air, to about 70° or 72°. In October, November and December, he lowers the temperature to 60° mornings and evenings, and 65° in sunshine."

2807. Griffin, as before observed, endeavors to keep the air of his fruiting and succession houses as near as possible to 60°.

2808. Baldwin says, "The fruiting-house, during the winter, should be kept at about 70°; it may be left in 75° in June, July, and August, and in the morning at about 65°, so that no attendance during the night will be required." (Cult. of Anan. p. 15.)

2809. Covering at nights. Speechly observes, that many small hot-houses are covered by large sheets of canvas, by the help of a roller and pulleys; * but where hot-houses are large, this mode of covering cannot so well be adapted; therefore the most general method is to use light covers of wood, or frames of wood, covered with painted canvas: the covering the whole of the roof of a hot-house in this manner is very troublesome, and attended with great expense; nor is it absolutely necessary, as I have observed above. When either of the above methods are practiced, it should be with discretion. In many places the covers of the hot-houses are sometimes, in a snowy, dark, severe, or rainy season, permitt ed to remain on for many days together, which is very detrimental to the plants, as they will in time draw themselves weak by the continuance of such a practice; for it is observable, that plants grow much faster, and in the the progress of plants when first they arise from seed, in the open ground, in the spring of the year, when they do not grow half so much in the day as in the night. But here it must be observed, that the sun and light give maturity to the nightly progress of plants, and the want of them soon causes the plants to grow languid, weak, and, in time, to die. If the covers of hot-houses be let down, there are times late in the spring of the year, which is injudiciously done in many places, even so late as the middle of the month of May; for as the covers are seldom taken off till after six o'clock in the morning (the hour that laborers come to their work at most places), it is very probable that many of the young shoots, from the time of their appearance in the fruit of the pine in blossom; for it should be remembered that light, as well as warmth, is essentially necessary to promote the growth of plants. In large double-pitted hot-houses, the covering of the lower lights may be effect ed with great ease, and this is found to be of use on a double account; first, because the fruit is in the front, but the fruiting very near the glass are in the middle of the house: and secondly, because the front pit is generally used for succession plants, which require severe weather; and, secondly, because the front pit is generally used for succession plants, which require..."
be shaded, after being shifted in the spring, whenever the weather is warm and clear, as I have before observed in treating upon that head."

2810. In Russia, the pine-stoves are frequently kept covered with boarded shutters day and night for several weeks, and even as long as three months together. As the plants are then as nearly as possible in a dormant state, it does not appear to injure them so much as a native of a more genial climate would imagine.

2811. Air. In March, when the plants are showing fruit, Speedy "admits a great quantity of air into the hot-house, the want of a due proportion of which causes the stems to draw themselves weak, and grow tall, after which the fruit never swells kindly." (Tr. on Pine, p. 50.)

2812. Abercrombie says, "Give plenty of air to plants in fruit, without a daily supply of which, they will not swell to a handsome full size, nor acquire the elevated flavor which belongs to the pine-apple when in perfection." (Abercrombie's Gard. p. 60.)

2813. McPhail admits air whenever it can be done consistently with attention to the temperature. In June, if the nights be cold, and the days cloudy, "you will have occasion for fires, otherwise you will not have enough, and the temperature." In July and August, abundance of air is given, and some often left at the houses all night.

2814. Nicol admits air at all seasons, in fine sunshine weather, "freely, as the fruit approaches maturity, in order to enhance its flavor."

2815. Grifith gives air to the fruiting-house, "discretionaly, in fine, mild, sunny days, from ten till about two o'clock," and more freely in the summer season.

2816. Baldwin gives air "when the weather will permit, winter and summer, from the back and ends, but never from the roof."

2817. Water. Speedeally says, "As the fruit and suckers begin to advance in size, the plants will require plenty of water to support them, which may be given at least twice, and sometimes three times a-week; but too much should not be given at one time; it is better to give them less at a time and oftener." As soon as the fruit appears full swelled, the watering such plants as produce them should cease; but it is a general practice (in order to have the fruit as large as can be got,) to continue the watering too long, which causes the fruit to be filled with an insipid, watery, and ill flavored juice. (Tr. on Pine, p. 59.)

2818. Abercrombie, between the times of watering plants in fruit, sprinkles the flues, but "suspects watering over the herb till the blossoms are fairly set. Afterwards, while the fruit continues green, it will be best of water to give water now and then, over the herb, from a fine rose-can; even despairs springing times. There is some restraint upon this; but after March has commenced, wash the herb perfectly clean every eight days. Use soft water that has been warmed to the temperature of the house; and, for two or three hours after, pour on hot water from the flues to exhale superfluous moisture. Moderate humidity and the suitable degree of heat will make the young fruit swell ample. At seasons when the mid-day sun has much power, it is best to water over the leaves as soon as the morning-sun is felt on the house, or two hours before sunset. The fruit will not swell off fine, if there be any deficiency in giving water. When the fruit is formed, forbear to water over the fruit or leaves; but it is still necessary to keep the earth about the roots a little moist. Nor, when the fruit is pretty large, should water be poured into the crowns so copiously as to stand in them more than one day. The different degrees in which the varieties stand in need of water must not be forgotten. As the pine-apples begin to ripe, put them on short allowance, for excessive humidity spoils the flavor of the fruit. Begin then the caution of decreasing the quantity; for, in hot weather, frequent small supplies should be given on account of the suckers on the plant, till consideration for the fruit forbid even sparing waterings, lest it should be rendered insipid.

2819. McPhail says, "Let it be remembered, that while the fruit is in blossom, and for some days afterwards, the plants should not be watered all over their leaves, neither should the plants be watered all over their leaves nor fruit after the fruit is fully swelled, nor should the earth, in which the roots are, be drenched with water; except very moist soil, they do not need water in the fruit-house, if its office, which it never has to do a second time." To water the fruiting pine-plants in winter; in gloomy weather, when it is best not to water over the leaves, a small-sized watering-pot, with a long tin spile and a flat nose on the end of it, should be in readiness: the water should be at 60°, and never under 60°. In January, they may require to be watered two or three times. The same in February. In March, wash them once or twice over the leaves, till every part be perfectly clean. They may require to be watered three or four times at root. In April and May, water over the leaves with water from 80° to 90°, and at bottom perhaps four or five times. In July, "when any of the fruit is fully grown, a pretty good size, water should not be poured into the crowns of the fruit so plentifully as to stand in them above a day or two."

In August, when the fruit are ripening, give no water.

2820. Nicol waters seldom in January, and not oftener than once or six or eight days in February, as he finds it may be given without danger. Give water rather copiously than heretofore advised, and also in larger quantities; generally a moderate watering at root once in three or four days, and a dwelling over head occasionally, to refresh the leaves, and keep them clean from dust. From the time the plants are out of flower, and the fruit begins to swell, water must be given continually to the three days following, to keep up the necessary quantity at root, and then a dwelling over head. Watering to this extent, however, if the fruit be not in too forward a state, will seldom be necessary before the end of the month, or till April."

In April, water must be given in a plentiful manner, once in two or three days, in order the better to swell of the fruit. The roots have now much to do in sustaining it, and also the suckers, which will be fast advancing in growth. For this reason, water frequently with dunghill drainings, or with water of dung, soaked on purpose; and after each watering at root, give a dwelling over the leaves, as directed above. In May, and June, and July, water over the plants once in four or five days, however, because of the great deterioration of water; and towards its being fit for cutting, withhold water entirely, else the flavor will be very much deteriorated. I shall here observe, with respect to the different kinds of pines, that the queen and the sugar-loaf sorts require considerably more water than the king or Hannavan, and the Arab, in order to the appearance in the crowns of waterings, and the perfect ripeness of the fruit, approach to maturity; as the latter-named kinds are naturally more juicy and watery than the former.

In August, the plants that have done fruiting being removed, the succession stock which replace them are to be watered freely at root, and occasionally dowe over top. In October and November, the waterings are generally lessened; and in December, once in eight, ten, or twelve days, will be sufficient. (Kal.)
Pinery — Fruiting Department

2821. Griffin never waters pines over the leaves in any stage, nor gives much of a damp weather. In other respects his practice agrees with that of Abercrombie and Nicol.  

2822. Baldwin says, "the plants in the fruiting-house cautiously filled towards February; but as the spring advances, gives a larger supply. He adds, "Never water your plants in the common broadcast method, over their heads and leaves." (Cult. of Awn. p. 21.)

2823. Treatment of the plants in fruit. "Sticks," Speechly says, "should be provided to support the fruit before it is grown too large; and in laying them, care should be taken to leave bandage room sufficient, making allowance for the swelling of the fruit. When the suckers are grown to a foot in length they should be taken off, and from that time the fruit will swell very fast." (Tr. on Pine, p. 51.) "Large fruiting plants," be adds, "will sometimes show their fruit in the months of August and September, but these are generally thought of no value, and consequently thrown away. To prevent this, I frequently take such plants out of the hot-house as soon as their fruits begin to appear. I then set them in a shed or out-house for five or six weeks; at the expiration of which time I pot them as in the month of March, after shaking off their balls. After this I plunge them into the tan; and in the month of March following put them into larger-sized pots, with their balls and roots entire. By this means I have sometimes cut tolerably good fruit from such plants in the months of May and June following. Such forward plants generally produce very fine suckers. Whenever the pine-plants are removed after they are grown large, it will be of service, before they are taken out of the tan-bed, to mark the side of the pots which stands next the sun; for it is observable, that the centres of the plants generally tend that way: so that the plants, when replaced, may stand as they did before they were removed. I do not mean that it is at all necessary for the plants to be put into the very identical places in which they stood before, but, in point of position, it will be proper, and the plants will be benefited by being so placed. This may as easily be done as placing them in a random manner, which is the common method."

2824. Abercrombie directs, "to keep the plants growing gently, and to have the pots, in general, com- pletly filled with the roots by the time at which you intend to excite them into blossom. From the middle of February to the 1st of March is a good time to have the main crop in flower; as the prospective season is the best for the fruit, during which time the fruit buds are fully formed, while the plants in pots by taking away two inches in depth from the top of the mould. Twist off some of the lower leaves. Fill up with fresh compost, round the stem, to the remaining leaves. The bark-bed should be revived at the same time, so as to make it lively; but no new tan should be added, till the time for the fullest heat arrives."

2825. If for any reason a pine-apple has been inveigled into bear fruit, do not show their fruit early enough in the spring or-fore-part of summer, to ripen their fruit before winter, when there is not sunshine enough to give the fruit any flavor. This may happen because the plants have not come to a proper growth, or their roots may have been injured by too violent a bottom heat, or by being over-watered, or they may have been forced too large, or for their roots to have been put into pots, before the end of the growing season. To make pine-plants show their fruit at an early time in the spring, some authors have recommended the cutting off some of the roots of the fruit-stalk, which were to be considered to be larger; and the cutting off of this roots, intended for fruiting the following year, be shifted late in the autumn into pots, which their roots do not fill well before the month of January, they probably will not show fruit till late in the spring or summer months." He tops-dresses the pots, and trims plants in February, and uses every means to heat water, &c. to keep them in a growing state during that month and March. If more than two or three suckers begin to grow out of the stem, they should be destroyed, unless they are so near the earth as to make roots into it, which will strengthen them without robbing the fruit. "In June, the fruit, when it gets large, should be supported with sticks to prevent it from falling, and to make the crowns grow up-right of the fruit. Were the fruit permitted to lean to one side, the crown in growing would force itself upright, and when the fruit is ripe, the crown would stand crooked on it. If any of the fruit that showed early are rape, set the plants out of the fruiting-house, and replace them by any that may have shown late."

2826. Griffin says, "the fruit of the ripe pine-apples is generally nothing better than the fruit of the pineapple, which has fruit, as your fruiting plants are now ripe, set out the pots, and take those in fruit from among your succession plants, to replace them. In November it may be well to have a few plants start into fruit, which may come in at an early and very acceptable season. Some may yet be green enough fully ripe, and should get no more water than is necessary to keep them from flagging."

2827. Time required to fruit the pine. All the authors quoted, excepting Baldwin, and almost all cultivators of the pine-plants, require from two and a half to four years from the planting of the crown or sucker to perfecting its fruit. The general period is from two and a half to three years; a fruit of the queen pine being gathered in August, 1819, and its crown put a few days afterwards, will, in the July, August, or September, 1822, produce fruit. A strong sucker from the same plant taken off, as is fre-
PRACTICE OF GARDENING. Part III.

quently the case, a month before the fruit ripens, and planted, will, in the end of 1821, or early in the spring of 1822, ripen its fruit.

2823. Baldwin, however, accomplishes this by both crowns and suckers in a shorter period, and appears to have great merit, not only in that, but in growing his succession plants without the aid of fire-heat. The following are his observations on both subjects. "The New Providence, black Antigua, Jamaica, Enville, and the other large sorts of ananas, will require the cultivation of three years to bring them to perfection, but, when once the king's or queen's new fruit has been produced, is only to be multiplied by suckers, which will ripen in fifteen months. To effect this it must be observed, that some of the plants will fruit in February or the beginning of March, and consequently that the suckers may be taken off in June, or the beginning of July. Make then a good bed with lining of litter round the outside, to keep in the sun; make the bed to fit a large melon-frame; put each bed in pots of about nine inches diameter, filled with the compost; plunge them in the bed prepared in regular order, and throw a mat over them in hot weather, for shade, till they have taken root; let them remain till the end of September, and then shift them into pots of about twelve inches diameter, and plunge them in the fruiting-house. I have had fine crops of pine raised from these suckers, many of which were made from the best suckers each season; I have only had this one plant, and expense, has greatly the advantage of the common plan of raising pines, in three years, by fires; when the fruit at last is frequently small and ill-flavored."

2824. It is a peculiar recommendation of this plan, that the plants reared in frames, without fires, the first year seldom or never run to fruit; whereas, on the contrary of this, the common practice is, to give them a large house, is seldom that one third of the plants come to the fruiting-house, because so many of them have run to fruit; and even those that stand are necessarily dried and stunted, being subject to the attacks of various insects; but, if they are taken off in time, and the sucking away, will then be prevented, and the fruit will be greatly benefited by this expedient."

2825. W. Hogg, who has grown the largest pines next to Baldwin and Buchan, "in March, 1830, had several of different sorts, which had been suckers taken from the parent plants in 1826, and which, under the usual treatment, had become too large to receive proper sustenance while remaining in pots. To provide a fit place for them, he cut a deep trench along the back of the bed, into which he put a quantity of good earth, and then turned the pines out of the pots into it, and filled up round the balls with mould of the same quantity, which he covered lightly with tan. At the time a few only of the plants were showing fruit, but they all (with the exception of one plant of the New Providence) fruited immediately, and extremely well, yielding fruit from 3 lbs. to 5 lbs. each in weight. The plant of the New Providence continued growing luxuriantly till the following February, when it showed fruit, which was cut in June, and weighed 9 lb. 6 oz. Due to the growth of this pine, it was twice nourished by a supply of fresh earth to its roots." (Hort. Trans. iv. 555.)

2826. Cutting ripe pines. "It is easy to know," Speechly observes, "when the pine becomes ripe by its yellow color, yet they do not all change in the same manner, but most generally begin at the lower part of the fruit; such fruit should not be cut till the upper part also begins to change, which sometimes will be many days after, especially in the sugar-loaf kinds. Sometimes the fruit will first begin to change in the middle, which is a certain indication of its being ripe; such fruit should be cut immediately.

2827. Abercrombie says, "The indications of maturity are, a diffusive fragrance, accompanied by a change in the color of the fruit; most sorts becoming yellow, or straw-color; others, dark-green, or yellowish tinge with red, or red-and-yellow; others, green and red-apple, or Russian red and green; the dead-red ones, or the greenish-yellow, or straw-color, they fall greatly off in flavor and richness; and that sharp luscious taste, so much admired, becomes insipid.

2838. Retarding and keeping fruit. "It sometimes happens," Speechly observes, "that great part of a stovel of plants will show their fruit at or near the same time, and with the same treatment, would consequently become ripe too nearly together. To prevent this, and bring them into a regular succession, when the fruit is nearly ripe, part of the plants may be taken out of the stovel, and set in a dry shady place; as, for instance, the stovel-shed, where the pots should be covered with moistened moss, but no water given them; it must be observed, that every one of the plants must be taken into the hot-house again, and set in the tan-bed for a week or ten days before the fruit is cut, to give it a good flavor. When there is a variety of hot-houses, this caution is not necessary."

2829. Abercrombie says, contrivances for retarding fruit, are sometimes resorted to, that plants which have started too soon into fruit, may have a better season to ripen in; and sometimes in order that a whole crop may not come in at once. The former may be provided for by shifting early in spring, or at any time before the fruit has taken firm; and the latter, if the diameter of the plant is too large, to make it a "If you perceive the fruit ripening too fast, or advancing too nearly together, set as many plants as you intend to retard into a dry airy place, affording both shade and shelter. Give no water as long as you wish to suspend their progress. For the same purpose, others may be set out green; while the excitement of these is lowered, they must be kept in a growing state."

2830. M'Phail observes, "If pines ripen too fast after one another, set the pots out of the house with the fruit on them, into an airy, cool, dry shade, and the fruit will keep a fortnight or longer, if it be set out before the fruit has a slight dew on it. In this situation, should have no water given them; and it may be necessary sometimes, in order to have a succession, or constant supply of fruit for a long time, to set some of
them out green, into a cooler place, to keep them back: and when you wish to ripen them, take them into the house, and plunge them in the tan again."

3825. **Size of the fruit.** Three pounds may be considered the average size of the queen pine-plates brought to market, eight to ten, but occasionally they grow much larger, attaining four and five pounds; and the Providence, with Specchly and Griffin, has weighed seven and nine pounds. Griffin appears to have been particularly successful in growing large fruit. At Kelham, near Nottingham, while growing pine-plates, he cut, in the year 1802, twenty queen pines, which weighed together eighty-seven pounds seven ounces; in 1803, he weighed five pounds three ounces; in July, 1804, one of the New Providence kind, weighing seven pounds two ounces; in August, 1804, one of the same kind, weighing nine pounds three ounces; and in 1805, he cut twenty-two queen pines, which weighed together one hundred and eighteen pounds eight ounces.

3826. **Baldwin.** At a meeting of the Horticultural Society of London, held in October, 1817, presented a queen pine of great beauty and superior flavor. It measured sixteen inches in circumference, seven inches in length, and weighed four pounds. The plant on which it was produced was little more than fifteen months old. (Hort. Tr. 1818.)

3827. *At the anniversary dinner of the society on the 4th of June, 1822, four New Providence pines were received from Baldwin, which together weighed 32 lbs. 10½ oz.; the largest 8 lbs. 14 oz.; the next 8 lbs. 5 oz.; the third 8 lbs. 2 oz.; and the fourth 5 oz. (Hort. Trans. 1823.)*

3828. **On the 17th July, 1821,** Wm. Buchan, to Lord Cowder, at Stackpool Court, Pembrokeshire, produced a pine which weighed 10 lbs. 8 oz. and was 10½ inches high, exclusive of the crown and stalk. This was larger than any pine which had been exhibited to the society, and with the exception of a few which have since been brought in, no finer, in the growth of the stock, or heavier, as far as has been seen, has been grown or fruited in this country. Buchan fruited three other Providence pines, of extraordinary weight, in the same season; one weighed 10 lbs. 6 oz.; another 10 lbs. 2 oz.; and a third 9 lbs. 8 oz. making the total weight of the four, 40 lbs. 8 oz. (Hort. Trans. v. 264.)

**SUBJECT. 8. General Directions common to the Three Departments of Pine-apple Culture.**

3829. **That which is general in the culture of the pine-apple chiefly respects the bark-pit, air, water, and insects.**

3830. **Management of the bark-pit.** The first point deserving attention here is the preparation of the tan, after it is brought from the tan-vats; but this has been already described. (See 1794.)

3831. **Formation of the bed.** McPhail says, "Pits for tan need not be made deeper than three feet six inches; if they be very wide, three feet will do; and to admit large fruited pine-plants, the surface of the tan-bed will require to be five or six feet from the glass above it. When a pine-pit is to be filled wholly with new tan, if it be late in the autumn or winter, the tan had best lie in a state of fermentation for some time before the pots be plunged in it. If pine-plants in pots be plunged in wet tan, it is apt to affect their roots, and if the roots be hurt, the plant must suffer."

3832. **Abercrombie says,** "It is desirable on the first formation of a bed, to mix new and old tan together; in which case the quantity of new bark to be brought into the pit will depend upon the goodness of the bark and bottom heat required. About one fourth of the parts of the bark-pit, with a mixture of old, rotten almost to earth, will produce a bottom heat of about 55°. When old tan with higher remains of strength is used to modify the new, the same heat may be produced, if the quantity of new be not more than half the capacity of the pit. This is said of a new pit. After a bark-bed has been in action, partial renewals of bark, to keep up the heat, are frequently sufficient in the reduced proportion of one third, one sixth, one twelfth, or less. At intermediate stages between the partial renewals, the bed requires only to be excited into a brisker fermentation by forking-up. About five sevenths of the pit from the bottom upwards, should be taken out, and the old bed renewed in its place; and about the sevenths from the top, or a little more than the depth of the pots, whatever that may be, should consist of old tan incapable of heating so as to burn the roots of the plants; at least such should be the ordinary distribution of the tan; but where peculiar circumstances require a speedy augmentation of heat, without disturbing the old beds, as when it is necessary to be swallowed off in the last stage, the earthy tan at top may be taken away, and new tan substituted."

3833. **McPhail has found,** "that when a tan-pit is about six feet wide, and three feet deep, filled with good new and old tan in nearly equal quantities, it is enough to raise and retain a sufficient heat for the growth of the pine-apple for a month or more, with the addition of as much new tan as will keep it up to its original height; at the expiration of which time, the exhausted part of the tan is to be taken out, and the bed renewed with new bark. When tan gets too dry, pour water into it now and then between the pots; this will cause a fine moist heat to arise among the plants to help to nourish them, and it will likewise enable the tan to retain its moist heat longer than if it were suffered to become dry, for no body of vegetables will continue to ferment and generate heat after the moisture in them is evaporated." (Gard. Remem.)

3834. **Temperature of the bed.** The general practice is to keep this from five to ten degrees higher than that of the air of the house in the winter months; somewhat higher in spring and autumn; and about the same temperature in summer. McPhail and Griffin prefer rather a higher degree of bottom heat. One hundred degrees, these authors recommend; or "about milk-warm, at the bottom of the pots, is heat enough for the roots of the pine-apple plant to grow in; therefore the depth, whether of tan, leaves of trees, or dung put into the pit, should be proportioned according to the quality of the material in regard to raising heat. If the air in the house be kept up to a proper degree of heat, the roots of the plants will grow in a heat of eighty degrees, so that it is safer to have the pots stand for a time in such a gentle heat than in a heat of upwards of a hundred; but let it be remembered, that the heat of the bed, especially from its surface to eight or nine inches downward, is liable to increase and decrease in a uniformity, though not so quickly, with the variations of the heat kept up in the atmosphere of the house. But be this as it may, the heat of the tan at the bottom of the pots when the roots are there, had best not be warmer than about milk-warm, especially in winter, when, if the roots at the bottoms of the pots be destroyed, there is not at that season of the year a kindly natural heat.
warmth in the house to cause young roots to spring from the stems of the plants to draw into them sufficient nourishment to sustain them; and farther, if the roots of fruiting plants be destroyed in winter, it will probably hinder them from showing fruit in time to ripen, or they will show weak."  

(Grad. Rem.)

2849. Abercrombie and Nicol agree in the following standard for the different classes of pines, allowing a latitude of from five to eight degrees, below or above:—Nursing bark-bed 75°; Succession bark-bed 78°; Fruiting bark-bed 82°. The standard for the succession-pit is fixed lower than that for the nursing-pit, to guard against the chance of starting the plants into untimely fruit. Abercrombie observes, that when the heat reaches 82°, it is of advantage to carry the pots a little higher than the top of the layer; but shorter than the top layer will scarcely exceed 65°. "Many persons," he adds, "work pine-stones with a bottom heat five or ten degrees higher than the maximum standard set down for each house above. These, on the one hand, the theorists, on the other, who censure the application of any bottom heat to exotics as unnatural, both seem to be in extremes. In tropical climates, the earth itself about the roots of plants is frequently so penetrated with the violent heat of the atmosphere, as to maintain a temperature of 90 degrees, or more, in the shade; consequently, for the roots of exotics from such climates to be plunged into a bed heated to that degree is not unnatural: still it should be recoleced, that the heat of the air there has a proportionate elevation of the heat of the earth. During our summer, therefore, instead of keeping the roots of pine-plants in a factitious heat of 80°, while the artificial temperature of the air is, in some cases, let down to 55° and 65°, perhaps a better relation of the bed with the atmosphere would be supported by having the bark-bed at 60° or 65°, and the air of the pit at 70°, at least never less than the heat at the roots."

2849. The measurement of bottom heat is effected by keeping trial-sticks in the bed, which McPhail considers sufficient for any experienced person; but the most accurate mode is, to plunge the bulb of the thermometer about a foot into the bed, till it reach that depth where the layer of old bark into which the pots are plunged, and the fermenting mass may be supposed to join. This will give the heat at the bottom of the pots.

2850. Renewal of the bark-bed. When the decline of the bed below a given temperature requires it to be renewed, take out the pots, tie the leaves carefully with bows, to protect them from being broken, and set them in a place where the plants will receive no check. If the top layer be earthy and decayed, so as to run through the screen, take it entirely off. Let the rest of the old bark be screened, and that which passes through be carried out of the house. Bring in new bark equal to the quantity taken away; but, before mixing it with the retained portion of the old, separate the least efficient of the old to serve as a top layer. Proceed then to mix the new bark equally with the soundest part of the old, turning over the bed from the bottom with a fork. Tread this part equally. To receive the pots, spread on lightly at top a layer composed three fourths of old bark, extending at least to the depth of the pots. Dress the surface of the bed full up to the sides of the pit, making it rather higher in the middle. After renewing a bark-bed, if there has been a great proportion of new tan introduced, or if there is any probability that the heat may rise excessively, plunge the pots but one third of their depth into the bark, or set them merely on the surface, till the full heat has risen and been found not in excess; then plunge them to the rims.

2851. Revising tan with the fork. If it be not requisite to take off the top, begin at one end of the bed, and dig out as much bark as will allow the remainder to be loosened, and completely forked over, without spilling any into the house. Fork it accordingly; return the bark taken out, level the top, and replunge the pots to their rims.

2852. Times of renewing and revising the bark-bed. After the bark-bed has been renewed by the substitution of new bark for that which is quite wasted, it may be expected to last in good action, with the help of an intermediate forking up, for ten or eleven weeks; consequently, it will require renewal about five times in the year. As a gradual decline must take place between one renewal and another, the heat can scarcely be kept by any management from fluctuating less than ten degrees; and therefore, in planning the business of the year, it is a desirable thing to distribute the times of renewal so that they may just precede those periods when something critical depends on having the bark-bed at a maximum heat. The principal occasions seem to be these:—

2853. The time of the principal annual potting and repotting, when established plants are advanced to the last and intermediate stages, and new plants are brought into the nursery-pit. This will commonly fall in the first week in August; but let it fall when it will, one of the fundamental reparations of the bed must be adapted to it; because the plants want a good growing heat to strike them, and the successive clearance of one pit after another affords the easiest opportunity for shifting the bark.

2854. That crisis of autumn when the weather is declining, yet not cold enough to light fires. This happens about the beginning of October, and may commonly follow too close after the entire restitution of the bed to admit of timing the second renewal exactly to it; the bed may be, however, well forked up, when the heat of the bed is at a maximum, the renewed layer will allow it to decline several weeks after the first. As it respects the fruiting-house, it should be particularly sound and complete, to allow of timing the third to a critical period in the culture of the pine. Rather protract the interval between the second and third renewal to three months or more, than precipitate the third, which might start the plants too soon into blossom. In the fruiting-house, according as you calculate that the plants will show fruit at the end of January or later, renew the bed just before, in the proportion of one third, if necessary, so as to have the bed steadily up to 80° when the plants come into flower.

2855. In March. A shifting of the roots into larger pots is frequently requisite for plants in the nursery and succession pits about the middle or end of March. Whenever repeated pots are to be struck, the bed should be prepared for yielding the approved degree of heat.

2856. In May. The same principle prescribes a renewal at the partial repotting, which is commonly made at the end of May. This may be combined with another object:—contribute to have the pit in lively action just before you discontinue fire-heat. As for forking up merely: if this be done at the end of six weeks
after renewal, there will be four or five weeks to run, while the heat is to be sustained on the old materials, which will be generally found a convenient distribution of this business. In the continued hot weather the hot-bed may be the fermenter that will require a greater supply of water, given out, from the mass of tan getting excessively dry. In this case, pour as much water on the surface, between the pots, as, in addition to that passing through the pots in common waterings, will restore sufficient moisture to the bed. With a small fork, keep the surface of the bark free from fungi, or crusty spawn, which are apt to generate there.

2857. Substitutes for tan. Tan is in many places scarce and dear, and in others not to be got; in either case it becomes an object to know the best substitutes, and their management. Horse-dung alone, as already observed, is used by some; and, by others, mixed with bark, with ashes, with leaves, sawdust, shavings, clippings of leather, chopped spray, and such other durable substances as can be brought to ferment along with it, and prolong its duration as a fermenting mass.

2858. Nicol, when tanners' bark is difficult to be procured, recommends a mixture of leaves with stable-litter, using about one-third of the latter (five to six or eight inches), in which to plunge the pots. But in using leaves, or leaves mixed with litter, they must always be well fermented, and the rank heat extracted out before they are made up for a bed for the plants.

2859. Nicol observes, that flax-dressers' refuse ferments very slowly and regularly, and that, used instead of stable-dung, it will keep up a steady heat longer than almost any other substance.

2860. Oak-leaves. Speckly used oak-leaves with great success, and gives the following directions for their preparation:

2861. After being raised into heaps, they should immediately be carried to some place near the hot-house, where they must lie to cough. I generally fence them round with charcoal-hurdles, or any thing else to keep them from being blown about the garden in windy weather. In this place we treat them well, and water them in case they happen to have been brought in dry. We make the heap six or seven feet in thickness, and with the hot-house, or anything else, more from the upper leaves from being blown away. In a few days the heap will come to a strong heat. For the first year or two that I used these leaves, I did not continue them in the heap longer than ten days or a fortnight; but in this I discovered a considerable inconvenience, as they settled so much when got into the hot-house, as soon to require a subsequent raising. I now believe if we have or the weather in the autumn, the leaves, or the matter they are to stand, beginning with the middle row first, and filling up the spaces between the pots with tan. In like manner we proceed to the next row, till the whole is finished; and this operation is performed in the same manner as when tan only is used.
2866. Decayed leaves make good manure; whereas, rotten tan is experimentally found to be of no value. I have often tried it both on sand and clay, also on wet and dry lands, and never could discover, in any of the cases of decayed leaves as manure; whereas, decayed leaves are the richest, and of all others, the most suitable for a garden. But this must only be understood of leaves after they have undergone their fermentation, which reduces them to a true vegetable mould, in which we experimentally know that the food of plants is contained. This black mould is, of all others, the most proper to mix with compost-earth, and I use it in general for pines, and almost for all plants that grow in pots: for flowers it is most excellent. The remainder of this vegetable mould may be employed in manuring the compartments of the kitchen-garden, for which purpose it is highly useful.

2867. Leaves mixed with dung make excellent hot-beds; and beds compounded in this manner, preserve their heat much longer than when made entirely with dung. In both cases, the application of leaves will be a considerable saving of dung, a circumstance very agreeable, as it will be the means of preventing the contests frequently observed in large families, between the superintendent of the garden, and the directors of the husbandry.

2868. Steam as a bottom heat, Speckly observes, "seems to stand forward among the modern improvements of gardening." Speckly knew, in 1796, only two instances in which steam was applied as bottom heat; and, with M-Thail, does not think it will finally answer as a substitute for tan. Instances in which it is adopted, are now much more numerous; but time sufficient has not elapsed, and the opinions of gardeners are yet too unsettled on its merits to enable us to recommend it for adoption in general practice. For heating the atmosphere of hot-houses, there seems little (or at least much less) doubt of its being preferable to fire-heat.

2869. Gunter, of Earl's Court, tried the application of steam as a bottom heat, by introducing the vapor into a chamber in the bottom of the pit, over which were laid cross bars covered with brush-wood, and, in some places, oak-planks, pierced with holes. On these the mould was placed in which the pines were planted. The quantity of heat imparted to the earth was very great, but, contrary to his expectation, no vapor ascended into the mould, which became excessively dry and husky; nor was he able, by frequent waterings, to keep it in a state fit for vegetation; the roots of the plants in it, in spite of every precaution, becoming shrivelled and dry. (Hort. Trans. iv. 408.)

2870. J. Hay, of Edinburgh, gives three examples (Calcd. Mem. vol. iii.) of steam having been adopted as a bottom heat in Scotland. It is there introduced under vaulted pits, or chambers covered with rafters and slates laid close in mortar, and has been found to succeed. (Different Modes of cultivating the Pine Apple, Ec. 174.)

2871. Hot water as a bottom heat. Count Zubow, at St. Petersburg, employed steam to heat a pit or cistern of water, over which, at about three inches' distance, a frame, covered with faggots, was placed, and on this was laid the earth, in which his pines and other exotics were planted without being in pots. The plan is said to have succeeded, and a wholesome temperature to have been obtained and communicated to the mould above the faggots. (Fischer, in Hort. Trans. iii. 430.)

2872. Fire-heat. Recourse must be had to the furnace whenever the temperature of the house, from the natural heat of the season, aided by the bark-pit, falls below 60°. At 55° the decline of atmospheric heat will not be got so far as to hurt pines and stovemats in general; but, if you light no fires till the thermometer fall to 55°, it may happen that, before the flames can be brought into full action to affect the house, a sudden retrocession in the natural season may sink the air at once five or six degrees lower — then, the tenderest exotics will be in a hazardous situation. It is not advisable to expose a plant that has been lately potted even to the extreme, 55°, lest it should be checked in making new roots. To refuse the aid of the furnace till the latest moment will also restrain the gardener from admitting fresh air, in the meantime, so as to have always pure air in the house. The maximum heat to be caused by fire alone in absolute winter, is 68°. This should be thrown to the middle of days not enlivened by sunshine; also, to periods when the heat of the bark-bed is from any cause deficient. The medium, 64°, for mere fire-heat, should be interposed on preparing to air the house in the forenoon; and in the evening, between three and eight.

2873. Pit-coal is the best kind of fuel, mixed with cinders of the same, on account of the duration of the fire and regularity of the heat: cinders are lasting in the next degree: peat may be resorted to under a deficiency of either of the others; it will require more attendance: wood blazes off so rapidly, that to maintain and regulate a furnace fed by it is very troublesome. (Pr. G.)

2874. Coal-dust, formed into bricks, with one third of its bulk of clay or pond-mud, has been tried by Knight. With these he found he could sustain a high and regular temperature in his pinery with little expense or trouble, and that the burnt clay and ashes were valuable as manure. (Hort. Trans. iv. 156.)

2875. Time of the day for lighting fires. As soon as fires become necessary, Abercrombie says, "the attendant on the furnace should set it at work every afternoon, at five, four, or three o'clock, according to the time of year, beginning an hour before sunset. His last examination of the furnace for the evening should not be earlier than ten o'clock, when as much fuel should be added as will support the proper heat till the morning, while the front of the fire is smothered with ashes to prevent too consuming a draught. He ought to be again at the fire, to refresh it with fuel in the morning, within
seven hours after leaving it; when the nights are longest, the decline of the fire will thus be repaired three hours before sunrise."

2876. The season for fire-heat falls mostly within the limits of eight months, specified below. Fire-heat is first resorted to in evenings; and is extended to mornings when the weather is cloudy and damp, or frosty. The lateness or forwardness of the seasons will require occasional deviations from any outline drawn from the practice of a single year: the following outline is given to assist, and not to fetter, the director of the stove:—

2877. October. As soon as cold nights or foggy days occur, fires will be wanted in houses where the standard atmosphere marks a high minimum. The pinery first demands the aid of the furnace, on account of all the plants having been recently potted. Gentle fires made in the evening, to last only for the night, will supply the few degrees of heat in which the natural climate is defective. Artificial heat is not applied to the house this time; to prevent this in the morning, through the roots from cold and damp. If the tan-bed send up a good heat, the use of the stove in the pinery may be deferred till the middle or end of the month. One object is, to keep the temperature up to a given minimum; another, to interfere with fire-heat when the declension in the natural climate is unsasonably abrupt. During the first part of the month, the temperature is more stable, and the use of the stove at the end of October.

2878. November. Work regular fires every evening, and occasional fires on cold mornings, and throughout the severe days. A violent heat would be pernicious. The maximum to aim at for the day-time, in rigorous frosts, is 65 degrees, independent of any rise in the thermomenter from occasional sunshine.

2879. December. Keep the ammunition fires in the furnace for the interim, late at night and early in the morning. Between five and nine in the forenoon, never let the course of the fire-heat relax: but if, between nine and three, the sun should shine sufficiently to raise the thermometer to 70 degrees, the furnace may be suspended, and not work again till three in the afternoon.

2880. January. Recruit and regulate the stove evening and morning. To have the heat defective, or in excess, would be alike prejudicial.

2881. February. The furnace must be carefully attended as the three principal hours of daily regulation come on the day, to maintain fire on all occasions.

2882. March. From the returning influence of the sun, and the gentle impulse of the stove, the plants will be excited strongly into growth. To conduct them by an equal progression, the fire-heat should be regularly sustained morning and evening, and, as noon approaches, to 70, 72, and 75 degrees, in case the power of the sun alone has not elevated the thermometer, by ten in the morning, at least to 70 degrees. To make the continuation of fire in a hot-house during the day depend merely upon the presence or absence of frost, is to treat a stove like a green-house. According to the climate to be imitated, the tenor of artificial heat ought to bear some analogy to the revolutions of temperature caused by the sun, as it regulates both the history of a day, and the rise and acme of a growing season.

2883. April. Continue fires regularly while the sun is down; and when the weather is chilly and gloomy, work the furnace all day.

2884. May. Continue with the evening fires: have a gentle heat in the early part of the morning, at least till appearances promise a fine warm day. Some managers, to spare fuel, dispense with the stove as soon as the thermometer can be kept, by the shelter of the house, and the influence of the bark-bed, from sinking below 60 degrees at the coldest time between sunset and sunrise. But, on the principle laid down in March, the hours and degrees are given. As the spring is advanced, indeed, where any fruit is forced that will repay the cost in the pinery, then, the minimum for May is 64 degrees at the beginning, and 68 at the close.

2885. June. If the weather be seasonable, no fire-heat will be wanted. But, if it be midsummer, according to the same cold influence from the atmosphere, in order to give sufficient air, without checking plants that have been excited by a higher temperature than that at which the natural climate may happen to be during an anomalous day or two. (Abercrombic.)

2886. Air. The following monthly directions on this subject by Abercrombic correspond with the practice of the other authors quoted:—

2887. July and August. You can scarcely give air without restraint, even in the day-time, at any other season of the year. The sun, even in July and August, is too hot for pines, and, therefore, leave openings for a gentle interchange with the unconfined atmosphere, so as not to expose the pines to casual rain. A constant circulation of pure air will always invigorate growing plants, and heighten the flavor of ripening fruit. In the middle of sultry days, keep down the heat to the maximum under Temperature, by a very free circulation of pure air.

2888. In September commences the necessity for caution in admitting air, so as not to lower the temperature below the minimum for the house. When air is given in reduced quantities, divide it equally to all parts of the pinery. The atmosphere at the autumnal is not equally cool as the vernal equinox, because the heat from the past summer is not at once dissipated. The 23rd of September will more often correspond with the middle of May than with the 21st of March, as to the influence on the glass of the withdrawing and returning heat in the natural climate. Proceed in September as in June and May below.

2889. October. To give air without hazard, see Temperature for the house, and the directions in April and March.

2890. November. In calm fine days, give moderate admissions of air from about ten till two. Be careful to shut the sashes, if the atmosphere turn cloudy or excessively cold.

2891. December. In the middle of a clear sunny day, when such occurs, though the air be frosty with it, slide down a light alternately a little way. Meanwhile keep up a maximum heat by the flames; and shut the glasses by two o'clock, or sooner, if the weather or the thermometer requires.

2892. January. As in December.

2893. February. As in November; rather freer: in order to which keep good fires.

2894. March. Watch for favorable opportunities to give air. In warm cheerful days, with a little wind, draw open some of the glasses about three hours before twelve, and close again by four in the afternoon; or, if the weather be suitably warm, as the situation shall decide, indeed, where it may be few.

2895. April. Every fair warm forenoon, as soon as the sun's influence will prevent the house from being chilled, admit fresh air by opening the sashes a little. From nine till noon, gradually widen the aperture for the air. Close again two hours before sunset, or before the thermometer is below 60 degrees, or the heat is increased by the forced advancement of the plants in particular houses. Whenever the weather is gloomy, raise the fire-heat preparatory to giving air.

2896. May. Fresh air may be admitted, in bright warm mornings, an hour sooner than in April; and, on fine afternoons, the sashes may be kept open proportionally later, so as the thermometer be watched, and the exceptions after shifting plants, or renewing the bark-bed, be attended to.

2897. June. Give air liberally from seven to six, if the weather has attained a seasonable settled warmth. When the thermometer is down to 66 degrees, shut the glasses for the evening.

2898. Water. The same agreement is observable in Abercrombic's general instructions.
tions for watering. "Use soft water; in winter, let water that is to be given to plants stand in the house to acquire the same temperature, or warm the water to 75 degrees before applying it."

2998. From November to February, or as long as the deficiency of a strong exhaling heat in the natural climate makes it unsafe to let water fall into the hearts of the plants, give the water through a tube, composed of jointed pieces, so that it may be shortened at will, and having a funnel into which you may pour water.

2999. From March to October it is proper to water over the leaves, excepting in the last stage of fruit and plants; let the water be warmed to 80 degrees before it is applied, which will contribute to kill several tribes of insects.

3000. From the middle of October to the end of February the plants will require to be moderately watered only once in eight or ten days. When they have been recently potted, they require less than at other times. Unless, and so far as they are of moist and soft soil, or weather, the plants may be kept without water for a lengthened interval, without any privation: in the beginning of October and March, once a week may be sufficient. During the course of September and April, they may require watering every five days; August, May, June, and July, every three or four. If, by accident, water fall into the heart of a plant in winter, the best mode to remove it from the house is to raise the temperature above the customary standard, that the water may go off in vapor before it can injure the plant.

3001. From the first of March to September is the season of free-excited growth, though this must commence sooner, or be continued later, according to the forwardness or delay of the plant, and the desired time of fruits, that during this season watered in the plants. until the bark-bed in good action, when you begin to water at the root in an increased degree; heat the air of the chamber nearly to the maximum, before you at any time dew the herb, and raise it fully afterwards; for, that visibility, corrected and exhusted by heat, will make the plants thrive.

3002. From May to August, the time of day of watering must receive more and more from the hour of noon to ten, nine, and eight in the morning; or to three, four, or five in the afternoon, according to the power of the sun. When July and August happen to be sultry, the pine, as a plant, will flourish the better for it. You may water in the evening or morning, but from pines in fruit withold water, as the signs of ripeness appear. In the height of summer, pour the water over the leaves, and into the centre of the plant. It promotes the health of the herb, to have water standing continually in the heart of the plant, under a well-sustained heat, never fluctuating more than ten degrees below 80°. Shut the house close after watering, which will cause a dewy exhalation.

3003. Watering with drainings of the dung-hill. In the growing season, about mid-day, between the times of shifting the plants, pour every six or eight days a quantity of dung-hill drainings on the mould, which is a compendious way of applying manure. Plants making new stalks and leaves may thus be invigorated; but after fruit is shown, only pure water should be given even at the root.

3004. Steaming the flues. Having the flues at a maximum heat, sprinkle them occasionally with water from a rose-pan. The steam thus raised is congenial to vegetation, and destructive to insects. It is a fine resource when you cannot water over the leaves. (Abercornia.)

3005. Insects. The white scaly coccus, or mealy pine-bug, is the most injurious insect to pine-apples. It adheres closely to the leaves; and if, not removed, will in time consume them, though in appearance it seems almost inanimate. It infests the vine, the orange, and many plants besides the pine; and lurking in the pots of earth plunged in the bark-bed, insinuating itself into every crevice of the walls and wood-work, is not to be extricated without extreme difficulty.

3006. The brown turtle insect, or brown scaly coccus, or bug, also infests the pine. It is nearly allied in form to the white scale, but is much less injurious in its effects.

3007. The white mealy crimson-tinged insect is also enumerated by Speechly; and by some is thought to be the same as the white scale, with which it is equally injurious, "wedging itself in between the protuberances of the leaves and the most surprising manner," so as not to be got out without great labour, eating the fruit unsightly, robbing its juices, and rendering it deficient in flavour, and ill tasted. (Try. on Pine, p. 133.)

3008. Destroying insects. So many different processes have been recommended for destroying these insects. that during this season. Do not deviate from the rules of Speechly. of the recipes and specified methods which have fallen into disuse, or were at once rejected by men of business, we shall avoid quoting any merely to say, that this is too simple to be effective, and that it is requisite to be of practical use, and a third as fatal to the plants as to the insects. It will be enough to select one or two remedies, which are safe, with a little qualification, and certainly efficacious. The ingredients of the first prescription are met with in many recipes: to Nicol belongs the credit of mixing them in the proportion recommended below. We shall previously observe, however, that Nicol's many experienced growers of pines concur in the opinion, that a chemical preparation is not to be resorted to till the effects of a sound, cleanly course of culture have been tried."

3009. Nicol's recipe. Take soft soap, one pound; flowers of sulphur, one pound; tobacco, half a pound; molasses, one ounce; soft water, four gallons; boil all these together till the liquor is reduced to three gallons; then add the soap to the liquor, and immerse the whole plant, after the roots and leaves are trimmed for potting. Plants in any other state, and which are placed in the bark-bed, may safely be watered over-head with the liquor reduced in strength by the addition of a third part water. As the bug harbors most in the angles of the leaves, there is the better chance that the medicated water will be effectual, because it will there remain in its consistency, and there its sediment will settle. The above is a remedy for every species of the coccus; and for most insects, on account of its strength and glutinous nature. Its application will make the plants look dirty; therefore, as soon as the intended effect may be supposed to have been obtained, remove the plant, and wash the liquor on the house. A second application would be improper to poor a decoction charged with such offensive materials over fruiting plants. Further, this peculiar dose for a tenacious insect is not to be applied indiscriminately to exotics in a general stove, as it might make the more delicate leaves of shrubs drop off.

3010. Griffin's recipe. To one gallon of soft rainwater, add eight ounces of soft green soaps, one ounce of tobacco, and three table-spoonsful of tannin; stir and mix them well together in a watering-pot, and let them stand for a day or two. When you are going to use this mixture, stir and mix it well again, then strain it through a thin cloth. If the fruit only is infested, dash the mixture over the crown and fruit,
with a squirl, until all is fairly wet; and what runs down the stem of the fruit will kill all the insects that are amongst the bottom of the leaves. When young plants are infested, take them out of their pots, and shake all the earth from the roots (tying the leaves of the largest plants together), plunge them into the above mixture, keeping every part covered for the space of five minutes; then take them out, and set them on a clean place, with their tops declining downwards, for the mixture to drain out of their centre. When the plants are dry, put them into smaller pots than before, and plunge them into the bark-bed. (Cult. Anan. p. 54.)

2913. Baldwin's recipe. Take horse-dung from the stable, the fresher the better, sufficient to make up a hot-bed three feet high to receive a melon-frame three feet deep at the back; put on the frame and lights immediately, and cover the whole with mats, to bring up the heat. When the bed is at the strongest heat, take some large sticks, open the cracked surface of the dung, so as to keep the plants from being scorched; set the plants or suckers, bottom uppermost, on the sticks, shut down your lights quite close, and cover them over with double mats, to keep in the steam; let the plants remain two days, take out the sticks, and wash them in a tub of cold water, previously brought to the side of your bed; then set them in a dry place, with their tops downwards, to drain, and afterwards plant them. This treatment is sure to kill every insect. You will observe likewise, that the crowns and suckers in the beds heated by linings of dung without fire-heat, will have all their insects killed, or be kept free of them, if they were clean when planted, by the effluvia of the dung. (Cult. of Aman. 33.)

2914. Miller's recipe. Miller recommends turning the plants out of the pots, and cleaning the roots; then keeping them immersed for four-and-twenty hours in water in which tobacco-stalks have been immersed; the bugs then are to be rubbed off with a sponge, and the plants, after being washed in clean water and dripped, are to be repotted. Muirhead, a gardener in the north of Scotland, has described a similar mode (Caled. Hort. Soc. Mem. i. p. 208), only in the place of tobacco-juice, he directs flowers of sulphur to be mixed with the water. With a bit of bass mat fixed on a small stick, and dip in water, he displaces as many as he can with this, and then places the plants in a tub of water, containing about 1 lb. of flowers of sulphur to each garden-potful. They remain covered with the water for twenty-four hours, as described by Miller. They are then laid with their downwardly, and are repotted in the usual manner. This mode of treatment is seen in the way in which the作者 renders the sulphur liquor does not clearly appear; the rubbing off or loosening the insects is evidently important; and it is not unlikely that immersion in simple water, so long continued, may alone be sufficient to destroy them. Indeed, the experience of one of the best practical gardeners in Scotland (Hay), leads him to conclude, that a simple immersion is destructive to these insects. During many years, he regularly watered his pine-plants over with the head, during the summer-months: this was done only in the evening; it never injured the plants; and the bug never appeared upon them. (Ed. Encyc. art. Hort.)

2915. Knight's suggestion. "Baldwin recommends the steam of hot fermenting horse-dung: I confine the destructive agent, in this case, is ammoniacal gas; which Sir Humphry Davy informed me he had found to be instantly fatal to every species of insect; and if so, this might be obtained at a small expense, by pouring a solution of crude muriate of ammonia upon quick-lime; the stable, or cow-house, would afford an equally efficient, though less delicate fluid. The ammoniacal gas might, I conceive, be impelled, by means of a pair of bellows, amongst the leaves of the infected plants, in sufficient quantity to destroy animal, without injuring vegetable life; and it is a very interesting question to the gardener, whether his hardy enemy, the red spider, will bear it with impunity." (Abercrombie.)

2916. Cleansing and refitting the house. Every department of the pinery must be kept at all times sweet and clean. At the period of removing sets of plants (or oftener, if necessary) that have completed specific stages, purify the house thoroughly, and have the flyce swept, the plaster white-washed, the wood-work and glass washed at all events, and the latter painted, if necessary, all broken glass mended, and every other substantial, or casual repairation effected. If insects are supposed to be harbored in the building, the following wash is to be introduced with a brush into the cracks and joints of the wood-work, and the crevices of the wall: "Of sulphur vivum, take 2 oz.; soft soap, 4 oz. Make these into a lather, mixed with a gallon of water that has been poured in a boiling state upon a pound of mercury. The mercury will last to medicate fresh quantities of water almost perpetually." (Abercrombie.)

SUBjcct. 9. Compendium of a Course of Culture.

2917. The following judicious summary of practice, from the planting of the crown to the cutting of the fruit, is given by Abercrombie. The dates are arbitrary; but specific days or months must be assumed to mark anniversary and other periods.

Oct. 30, 1813. If the plants, from forward growth, require more room, some are removed to another pit, and the remainder set in the nursery.
March 30, 1814. Such plants as want to be shifted. Plants of the same standing are now sometimes distributed to houses where the treatment differs, as the plant is expected to fruit at the end of two or three years. 1. The large black varieties require three years' culture. 2. Crowns and fruit-suckers are seldom so forward as suckers from the stem. The last, indeed, commonly grow very vigorously, and do best under a moderate excitement during the first two stages.
2919. Three-year fruiting plants. Nursing-pit. May, 1814. Plants intended to complete a year in this pit, are repotted, having the ball of earth shaken away, and all the root-fibres pruned off.
2920. Nursing-pit. Aug. 15, 1814. Plants that have been in the nursery-pit the previous year, are shifted and transferred to this house.
2921. Fruit-house. Aug. 1815. Plants which have consumed one year in the nursing-pit, and a second year in the nursery-house, are removed to this department.
2923. Two-year fruiting plants. Succession-pit. March 30, 1814. Plants from the nursery-pit are put into larger pots; and brought for culture here, as directed under this division.
May or June, 1814. Succession paris are sometimes intermediately shifted, without disturbing the balls of earth.
2924. Fruit-house. Aug. 15, 1815. Plants from the succession-pit, having consumed one year in the first and second stages, are shifted into the largest-sized pots, to be treated as under this head. Aug. 1. 1815. Having been cultivated as under fruit-house, the ripe fruit is fit to cut.
2925. The effect of a very high temperature during the day, in bright weather, and of comparatively low temperature during the night, with many rainy weather, and the air and water, is to render the house a temperature of about 70°, during summer, was employed; but no air was given, nor its escape facilitated till the thermometer, perfectly shaded, indicated a temperature of 95°; and then only two of the upper lights, one at each end, were let down about four inches. The heat of the house was consequently somewhat raised to 115°, the picture being of warm and bright light, in a room it generally varied, in such days, from 95° to 105°, declining during the evening to about 80°, and to 70° in the night. Late in the evening of every bright and hot day, the plants were copiously sprinkled with water, nearly of the temperature of the external air. The melon, water-melons, Guernsey lily, fig-tree, nectarine, melon, lemon, and other hardy deciduous plants, natives of temperate climates, grew in this hot-house so managed "through the whole summer, without any one of them being drawn, or any way injured, by the very high temperature to which they were occasionally subjected; and from the fact that, during all the hot weather, and from the other experiments of which I am aware, it is my observance, I think myself justified in inferring, that in almost all cases in which the object of the cultivator is to promote the rapid and vigorous growth of his plants, very high temperature, provided it be accompanied by bright sunshine, may be employed with great advantage; but it is necessary that the glass should be of good quality, and that there must be a constant supply with sand and water." In the above case liquid-manure was employed. It is added, My house contains a few pine-apple plants; in the treatment of which I have deviated somewhat from the common practice; and I think with the best effects, for their growth has been exceeded, indeed, by none, and by many that many gardeners who have cultivated apples, and tree and shrub plants of which the manner in which the pine-apple plant is usually treated, and very much disposed to believe the bark-bed, as Kent has stated (Hort. Trans. iii. 288.), "worse than useless," subsequent to the emission of roots by the crowns or suckers. I therefore resolved to make a few experiments upon the culture of that plant; but as I had not received a single plant before the beginning of March, and I had not then observed, in the flower of the pineapple, any hint of the fact that the cold of January was the nurse of the pineapple. My hot-house was not completed till the second week in June (1819), at which period I began my experiment upon nine plants, which had been but very ill preserved through the preceding winter by the gardener of one of my friends, with very inadequate means, and in a very inhospitable climate. These, at the time they were not larger than some which I have subsequently raised from small crowns, (three having been afforded by one fruit,) planted in the middle of August, were in the end of December last; but they are now beginning to blossom, and in the opinion of every gardener who has seen them, promise fruits of very great size and perfection. They are all of the variety known by the name of Ripley's queen pine.

2926. Upon the introduction of my pine-plants into the hot-house, the mode of management, which it is the object of the present communication to describe, commenced. They were put into pots of somewhat more than a foot in diameter, in a compost made of thin green turf, recently taken from a riverside, chopped very small, and pressed closely, whilst wet, into the pots: a circular piece of the same material, of about an inch in thickness, having been inverted, unbroken, to occupy the bottom of each pot. This substance, so applied, I have always found to afford the most efficient means for draining off superfluous water, and subsequently for facilitating the removal of a plant from one pot to another, without loss of roots. The surface of the reduced turf was covered with a layer of vegetable mould obtained from decayed leaves, and of sandy loam, to prevent the growth of the grass roots. The pots were then placed to drain the water away, near the wall, where the temperature of the air was capable of being reduced as the height of the plants increased. The temperature of the house was generally raised in hot and bright days, chiefly by increased solar heat, from 95 to 105 degrees, and sometimes to 110 degrees, no air being ever given till the temperature of the house exceeded 95 degrees; and the temperature of the house was then increased to a slight degree beyond the temperature of the house generally sunk to 70 degrees, or somewhat lower. At this period, and through the months of July and August, a sufficient quantity of pigeons' dung was steeped in the water, which was given to the plants at first, to raise its temperature to that of the air, and when this they were usually supplied twice a day in very hot weather; the mould in the pots being kept constantly loose, or which was generally called wet. In the evenings, after very hot days, the plants were often sprinkled with clear water, of the temperature of the external air; but this was never repeated till all the remains of the last sprinkling had evaporated, as a great number of the plants, having received the beneficial effects of the gardens, to give their pine-plants larger pots in autumn, and this mode of practice is approved by Baldwin. (Coll. of Ann. 16.) I nevertheless cannot avoid thinking it wrong; for the plants, at this period, and subsequently, owing to want of light, can generate a small quantity only of new sap; and consequently, which cannot be done in the new pots, new roots, however weak, the new mould, must be drawn chiefly from the same reservoir, which is to supply the blossoms and fruit: and I have found, that transplanting fruit-trees, in autumn, into larger pots, has rendered their next year's produce of fruit smaller in size, and later in maturity. I therefore would not remove my pine-plants into larger pots, although those in which they grow are considerably too small. As the length of the days diminished, and the plants received less light, their ability to digest food diminished. Less food was in consequence dissolved in the water, which was also given with a more sparing hand; and as winter approached water only was given, and in small quantities.
2923. During the months of November and December, the temperature of the house was generally little above 50 degrees, and sometimes as low as 49 degrees, and once so low as 40 degrees. Most gardeners will know that this is very unfavourable to the growth of their plants, and that, therefore, it is much more desirable that plants should be heated, in December, than in June. It is almost as much harderplant as it is usually supposed to be; and I exposed one young plant in December to a temperature of 22 degrees, by which it did not appear to sustain any injury. I have also been subsequently informed that Dr. J. D. False, of Philadelphia, who has had many years experience of raising plants in cold frames, and that he has frequently seen, in the East, the pineapple growing in the open air, where the surface of the ground, early in the mornings, showed unequivocal marks of a slight degree of frost.

2930. My plants remained nearly torpid, and without growth, during the latter part of November, and in January; but got up early in July. Several of these plants, which I had kept in a room all winter, and though the house rarely reached 60 degrees; and about the 30th of that month, the blossom, or rather the future fruit, of the earliest plant, became visible; and subsequently to that period their growth has appeared very extraordinary to gardeners who had never seen pine-plants growing, except in a bark-bed or other hot-bed. I have observed above 50 degrees, during this month, and if the temperature, materially increased to that of the bark-bed, their roots, owing to their having passed the winter in a very low temperature comparatively with that of a bark-bed. The plants are now supplied with water in moderate quantities, and holding in solution a less quantity of water than would be supplied for their use.

2931. In planting suckers, I have, in several instances, left the stems and roots of the old plant remaining attached to them; and these have made a much more rapid progress than others. One strong sucker was thus planted in a large pot upon the 20th of July (1819), and that is (March 1830) beginning to show fruit. Its stem is thick enough to produce a very large fruit; but its leaves are short, though broad and numerous; and the gardeners who have seen it, all appear wholly at a loss to conjecture what will be the value of its produce. In other cases, in which I retained the old stems and roots, I selected small and late suckers, and these have afforded me the most perfect plants I have ever seen; and they do not exhibit any symptoms of disposition to fruit prematurely. I am, however, still ignorant whether any advantage will be ultimately obtained by this mode of treating the queen pine; but I believe it will be found applicable with much advantage in the culture of those varieties of the pine, which do not usually bear fruit till the plants are three or four years old.

2932. So-called remarks are next made upon the facility of managing pines in the manner recommended, and upon the necessary amount of the expense. "My gardener is an extremely simple laborer, he does not know a letter or a figure; and he never saw a pine-plant growing, till he saw those of which he has the care. If I were to leave him at his present maturity to his own devices, I should lose but in every other respect he knows how to manage the plants as well as I do; and I could teach any other untrained gardener the same. I have had the most intelligent and attentive laborer, in one month, to manage them just as well as he can: in short, I do not think the skill necessary to raise a pine-plant, according to the mode of culture I recommend, is as great as that requisite to raise the pineapple, or a pine-plant for my friend I. D. False, whose pineapple, which was twelve wide, is rather less than sevenpence a day here, where I am twelve miles distant from cool-pits: and if I possessed the advantages of a curved iron-roof, such as those erected by Loudon, at Bayswater, which would prevent the too rapid escape of heated air in cold weather, I entertain no doubt, that the expense of raising a pine-plant of this kind, from suckers, would be a mere alembic. In the case of the pine-plants, exclusive of grapes or other fruits upon the back wall, would not exceed fourpence a day. A roof of properly curved iron bars, appears to me also to present many other advantages: it may be erected at much less cost, it is much more durable, it requires much less expense to paint it, and it admits greatly more light. November has since (March 1830) had 72 degrees, which has been recorded in the bar, hinted at erected, and curled with our bar; and in a long paper (Hort. Trans. iv. 543.) read in November, 1821, and two others (Hort. Trans. v. 142. 227.) he has given some account of it, and of his experience in pine-plant culture: the above paper, is quoted at length in The Difficulties and Advantages of raising the pine-plant (from its first introduction to Europe, to the improvements by T. A. Knight, in 1822, which should be in the hands of every pine grower,) and the following remarks are from that work:"

2933. To draw any conclusions in the present stage of Knight's experiments would be premature, and might excite prejudice to anticipate the final result. That the pine-plant will grow and thrive, with what is out technically called bottom heat, is an obvious truth, since no plant in a state of nature is found growing in soil warmer than that of the superincumbent atmosphere. But to imitate nature, is not always the same as imitate her. The imitation, of course, extends to the care, and the mode of dressing, of her products, at least as far as horticulture is concerned. What would our cobby, cabbage, and apples be, if their culture were copied from nature? Though the pine-plant will grow well without bottom heat it may grow with bottom heat still better; and though the heat of the earth, in its native country, may never reach a degree, that in our state it does not find a place in the air, or in the atmosphere, it may not be of service to it, in a state of artificial culture. But admitting for the sake of argument, that the pine-plant could be grown equally well with, as without bottom heat; still it appears to us that the means of retaining bottom heat, and using it, does not appear to be most suitable for the purpose, as being a perpetual fund of heat for supplying the atmosphere of the house in case of accident to the flues, or steam-apparatus.

Besides it appears from nature, as well as from observing what takes place in culture, that the want of a steady temperature and degree of moisture in the roots of plants is more immediately and directly injurious to it, than any deviation in its daily or hourly course. The soil, as frequently as possible, is to be kept as loose and full of air as possible, and kept in a warm state, as the evaporation from the surface and sides of the pot, and the transpiration of the plant goes on, it becomes gradually less and less so, and if not soon repleted, would become dry and shrivelled, and either die from that cause, or be materially injured by the sudden and copious application of water. Thus the root of the plant, that is properly constituted and regularly pulvcrized soil, whatever quantity of rain may fall on the surface, the soil is never saturated with water, nor, in times of great drought, burnt up with heat. The porous texture of the soil, and sub-soil, being at once favorable for the escape of superfluous water, and adverse to its evaporation, by never becoming so much heated on the surface, or condensing moisture, as to superheat the earth, the surface of the earth, the temperature of which never can be completely attained by growing plants in pots, and least of all by growing them in pots surrounded by air. In this state, whatever may be the care of the gardener, a continual succession of changes in the temperature of the roots, and of the pot, takes place, and the temperature being composed a much more rapid conductor of heat than porous earth, it will soon be communicated to the web of roots within. With respect to water, a plant in a pot surrounded by air is equally liable to it. If the soil be properly constituted, and the pot properly drained, the water passes through the mass as soon as it is poured, and is, as Mr. Sowerby says, to be desired that it should be so. If the surface of the plant be made as smooth as possible, and if the evaporation be hastened by the evaporation from the sides and surface of the pot, the temperature which always would be the average temperature of the air of the house, and the re-
tention, by the same means, of the steady degree of moisture, would, in our opinion, be a sufficient argument for plunging pots of vigorous-growing, many-leaved, or fruit-bearing plants.

2934. Had Knight's plan been brought forward by a less eminent horticulturist, it would have claimed but little attention, as the plan of growing pines without bottom heat, is generally considered to have been tried,—first by M. Le Cour, and subsequently by various others, and abandoned. In Knight's hands, however, whether it fail or succeed, it is certain of doing good, by the observations it will elicit from the fertile and ingenious mind of so candid and philosophical a horticulturist. (The different Modes, &c. p. 170.)

2935. Estimate of Knight's efforts as to the culture of the pine-apple. Knight's two subsequent papers contain merely incidental observations of little consequence; but in so far as they go, rather adverse than otherwise, both to the plan of house, as well as the mode of culture. On the whole, it may safely be asserted that no light has been thrown on the culture of the pine-apple by this eminent horticulturist, notwithstanding his assertions respecting the great facility of its culture by the most ignorant laborer; that the culture in the bark-bed, or other hot-bed, if the pots be plunged into it, is worse than useless (Hort. Trans. iv. 544.); and that every one of a very great number of gardeners who visited the garden, declared himself a zealous convert. (Jb. 555.)

The truth is, Knight commenced his operations a perfect novice in that department of gardening; and it is most curious to observe, from his own accounts, that he has only succeeded in so far as he has approached to the modes in common use. Very large pots were adopted (Hort. Trans. v. 144.), which served as an approach to plunging smaller pots in a mass calculated to preserve a uniform degree of moisture: a house with a fixed roof is found less suitable for ventilation than one with sliding sashes (Hort. Trans. v. 287-8-9.); and this circumstance, and that of the iron bars admitting so much light, render the risk of over-heating such, that it was "thought best" to be "provided with a net" to shade in hot weather. In short, notwithstanding the "many converts" among the "practical gardeners," and the confident assertions in the communications to the Horticultural Society, the failure may be considered as not only complete, but as having been attended by nothing useful or new on the subject. It is but rendering justice to practical gardeners to state this freely; and Knight is too sensible a man to be offended at us for having done so. We, therefore, recommend all those who wish to grow the pine-apple in the first style of excellence, and at a moderate expense, to adopt the pits and houses of Baldwin, Alton, or Scott; and to imitate their practice, or that of M'Phail and Griffin. See the useful treatise above (2932.) referred to for more minute details.

2936. The mode of employing the vigor remaining in the old stock or plant after the fruit is cut, to nourish, for a certain time, the sucker or suckers which may be growing on it, was practised by Speechly; but scarcely to the extent to which it has been carried lately. This we think, a considerable improvement, if kept within certain limits; but, if carried too far, what might be gained by the sucker coming earlier into fruit, would be lost by the retardation of its own suckers.

2937. A queen pine, grown by Peter Marsland, of Woodbank, near Stockport, was exhibited to the Horticultural Society, on Nov. 3, 1818. "It weighed three pounds fourteen ounces, measured seventeen inches in circumference, and was peculiarly well-flavored. The singularity of this pine was its being the produce of a sucker which had been removed from the parent root only six months previous to the time the fruit was cut. The plant on which the sucker grew had produced a fruit, which was cut in October, 1817; the old stem, with the sucker attached, was allowed to remain in the pine-pit till May, 1818; at that time the sucker was cut off, potted and plunged into a fresh pit; it ripened a fruit, which, in the course of four months, attained to the weight and size above stated. P. Marsland is in the practice of producing pines in this way with equal success and expedition. His houses are all heated by steam." (Hort. Trans. v. 579.)

2938. Specimens of the New Providence, globe, black Antigua, and Easville, were exhibited on the 17th of October, 1819, all which were produced in a similar manner to the above. P. Marsland considers, that "though not of the largest description, yet as far as beauty of form and richness of flavor are concerned, they would not yield to fruit of more protracted growth." The success which has attended this gentleman, in exhibiting two of the plants, not only to entitle two of the plants, not only to entitle them to a place among the great fruit of the year, but on the cutting of their previous produce, has been perfectly satisfactory; and the following is his account of it. "In November, 1819, as soon as the fruit had been cut from the pine-plants, which were then two years old, all the leaves were stripped off the old stocks, nothing being left but a single sucker on each, and that strongest on the plant; they were then placed in a house where the heat was about sixty degrees, and they remained till March, 1820. At this period the suckers were broken off from the old stocks, and planted in pots from eight to twelve inches in diameter, varying according to the size of the sucker. It may be supposed, however, to observe, that the length of the sucker, when attached to the mother plant, depends in some degree upon the kind of pine: the tardy fruiters, such as the black Antigua, and others, require to be left longer than the queen, and those which fruit readily. Aft the suckers had been planted, they were removed from the house, where they had remained while their striking root, the largest of the suckers showed fruit, which swelled well, and ripened between August and November, being, on the average, ten months from the time the fruit was cut from the old plants. The fruits from the sucker, though, as may be expected, not of the largest description, I have invariably found to be richer and higher flavored than that grown on older plants. The suckers of inferior strength will not show fruit in the same season, but in the following they will yield good fruit, and strong suckers for a succeeding year's supply. Those suckers are to be preferred which are produced on plants that have ripened the fruit in November, for those taken from plants whose fruit is cut in August or earlier, are apt to show fruit in January, or..."
February, while yet remaining on the mother plant. But whenever this happens, the sucker should be broken off immediately upon being perceived, and planted in a pot so as to form a root of its own, to maintain its fruit.” (Hort. Trans. iv. 392.)

2393. This experiment shows what can be done; though it must be obvious that a considerable part of the saving in time is lost by the small size of the fruit. Baldwin, in our opinion, has hit on the proper use of this property of which we have spoken, consists in the improvement of the shrivelled, lost vigor of the old stock. He contrives to produce tolerably sized fruit, and to have such a degree of vigor in his suckers, that as they are able, in their turn, to throw out other vigorous suckers to succeed them. In aid of this, he first earths up the old stock, so as to cover the lower end of the sucker; and partially wrenching it off, so, by these means, obtains for it a good stock of roots before he renders it an independent plant.

Sect. 11. Of the Culture of the Vineyard.

2394. On the culture of so important a fruit as the grape, it is not surprising that there should be a great variety of opinions. Without quoting those of the earlier, and of foreign authors, neither of which are of much value as to the hot-house culture of this plant, we shall give those of the best modern British gardeners; on the general modes adopted of culture in ordinary vineyards; in regard to particular modes of culture; as to gathering and preserving the fruit; and as to insects and diseases.

Subsect. 1. Of the General Culture of the Grape in Vineyards.

2391. The culture of the grape in ordinary vineyards embraces the subject of soil, sort of grapes, sort of plants, pruning, training, bleeding of the shoot, culture of the borders, time of beginning to force, temperature, air, water, ripening and resting of the wood.

2392. Soil. The kind of compost Speckley made use of for the vine border of the hot-house was a Welbeck, as follows, viz. “One fourth part of garden mould (a strong loam); one fourth of the swarth or turf, from a pasture where the soil is a sandy loam; one fourth of the sweepings and screenings of pavements and hard roads; one eighth of rotten cow and stable-yard dung, mixed; and one eighth of vegetable mould from reduced and decayed oak-leaves. The swarth or sward should be laid on a heap, till the grass roots are in a state of decay, and then turned over and broken with a spade; then put it to the other materials, and work the whole well together.” (Tr. on Vine, p. 25.)

2393. Boscromble says, “Materials and proportions of a good compost are of top-spat sandy loam from an upland pasture, to make three parts; one part unexhausted brown loam from a garden, one fourth part; screenings of roads, free from clay, and repaired with gravel or slate, one sixth part; vegetable mould, or old tan reduced to earth, or rotten stable-dung, one eighth part; shell-marl or mild lime, one twelfth part.” The borders he recommends to be from three to five feet in depth, and, where practicable, not less than four feet wide in surface within the house, communicating with a border outside the building, of not less than ten feet wide.

2394. M'Phail directs as follows: “To make a suitable border where it is required for the grape-vine, provide a large quantity of earth of a loamy nature; that from arable land, or from a ridge in which a hedge-row of hazel, maple, elm, &c. have grown many years, and have been grubbed, is good; or a spit deep from the surface of a common, long pastured; or from the head or end lands of a corn-field; either of these will do very well.” For forcing early, he adds, “Vines do best in a strong deep loam, not destitute of a mixture of sand, and well manured with rotten dung, on a dry bottom of hard clay.”

2395. Nicol, after premising that the bottom of the border is to be made perfectly dry by draining and paving, says, “the average depth of the border should not be less than a yard. If four feet, so much the better; and it is just sufficient to say how broad it should be; but it should not be narrower, outside and inside of the house taken together, than thirty feet. The soil should be thus composed: one half strong hazel loam, one fourth light sandy earth, an eighth part vegetable mould of decayed tree-leaves, and an eighth part rotten dung, to which may very properly be added, a moderate quantity of lime, or of shell-marl. These articles should be perfectly decomposed, and intimately mixed, before planting.”

2396. Griffin, who has received the medal of the Horticultural Society for his skill in cultivating grapes at Woodhall, in Hertfordshire, forms his vine borders as follows: After being completely drained, the whole bottom is covered with brick, stone, or lime rubbish, about six inches thick, and on this is laid a compost of “half good loamy soil with its turf, one quarter of rich solid old dung, and one quarter of brick and lime rubbish; the turf well rotted, and the whole well incorporated.” (Hort. Trans. vol. iv. p. 100.)

2397. Judah uses half of rich gritty loam from a common; a quarter of rich old dung; and a quarter of lime rubbish, tan, and leaf mould, mixed together. These materials were kept separate, and frequently turned during winter, and when afterwards well mixed were not sifted, but laid on a prepared bottom to the depth of three feet. He says he does not use so much dung as is usually done, because, though the vine will soon use up the qualy manure, yet its growth is thereby retarded, especially when young. He recommends the addition of old tan, from having experienced (with Speckley, Mitchell, and others) that the vine will root in that more freely than in any other substance. (Hort. Trans. vol. iv. p. 4.)

2398. Sort of grapes. In the horticultural catalogue will be found a description of the best sorts of grapes for forcing, or the open wall, from which a selection may be made, according to the taste of the party.

2399. For a mere glass case, in which the fruit is to be ripened by the heat of the sun, the following, which are the hardiest sorts, will succeed best, viz. white muscardine, white sweetwater, black sweetwater, black Hamburgh, large black cluster, black July, miller grape, and black St. Peter's.

2400. For a small house to be forced, or to which fire-heat is to be applied in spring and autumn, the following sorts are what experienced gardeners recommend, as sure bearers and high-flavored grapes: black and red Hamburgh, black and grizzly Frontignac, black prince, white muscat of Alexandria, Sitwell's white sweetwater, and early white Teneriffs.

2401. M'Phail, for general forcing, recommends, as “the best sorts of grape-vines for the black
Hamburgh, red Frontignac, black prince, black muscadel, red Lombardy, royal muscadine, white muscadine, white Frontignac, white muscat, white sweetwater, white muscadel, and white Syrian. (Gen. Rev. P. 7.)

2592. Nicol, for general forking, names twenty-four sorts, as under, marking those he esteems the best with an asterisk (*).

2593. Speed, Forsyth, and Abercrombie give long descriptive lists, and leave the reader to choose from their descriptions.

2594. Sorte of plants. Vines are to be had in the nurseries, propagated either from layers, cuttings, or eyes; and provided the plants be well rooted, and the wood ripe, many are of opinion that it is a matter of indifference from which class the choice is made. Justice prefers plants raised from cuttings, as likely to have ripened roots; but where they have to be sent from a distance, he prefers to plants, cuttings containing an inch or two of the old wood, and twelve or fourteen inches of the new. These he plants at once where they are to remain, as practised in France. Speedy prefers plants which have been raised from the eye, for the following reasons: "They have more abundant roots, grow shorter jointed, are more prolific, and will, if permitted, come into bearing the second year." Abercrombie takes indifferently plants raised from cuttings or eyes; and McPhail does not direct any preference. Nicol approves of "plants raised from cuttings that have been two seasons in pots, and have been properly treated and trained to a single shoot." The shoot of the first year should have been headed down to within six or eight inches of the pot; and that of last season to four, or, at most, five eyes. "The plants should have been fresh potted into good earth last season, and should be now in pots of nine or ten inches diameter, well rooted, and healthy. Such plants are much to be preferred to those raised from layers that are seldom well rooted, and never grow so freely as plants raised from cuttings."

2595. Cuttings and eyes. It may be remarked, that the most general mode of propagating the vine at present, in the best nurseries, is from buds or eyes; and that, both as the cause and effect, such plants are made choice of by most gardeners. The great objection to layers is, that being propagated in the open air, they grow till checked by frost, and then do not ripen their roots, which generally die off; so that the plants make very weak shoots the first year after planting. Layers kept in the nursery one year after being separated from the mother plant, are, of course, not so liable to this objection. Plants raised from cuttings or eyes, having no adventitious support, produce no more roots than what the shoot and leaves enable them to ripen, and at two years' growth, may be justly considered as the best description of plants for stocking a house.

2596. Expeditious propagation. Neill (Edin. Encyc. art. Hort.) describes "an incomparably more speedy mode of storing a new grape-house," than that of employing any description of plants to be procured from a nursery.

2597. This mode is only to be adopted *where a vineyery previously exists in the neighborhood. It is practised frequently at the gardens of Dalkeith House, by James Maxwell, head gardener, and a distinguished Horticultural Society; and Neill has been an ocular witness of its complete success. In the end of June or beginning of July, when the vines have made new shoots from ten to twelve feet long, and about the time of the fruit setting, he selects any supernumerary shoots, and, having loosened them from the trellis, bends them down so as to be changed almost at pleasure, and next season the house would yield a full crop of grapes. It is not meant that they should be allowed to do so, if permanently bearing plants be wished for; on the contrary, they are to be suffered to carry only a moderate crop, as it is very evident that the roots could not sustain the demand of a full one, or at any rate, that the plants would necessarily show their exhausted state, by barrenness in the following season. By this means the more delicate kinds, as the Frontignacs, may be quickly propagated; and we have seen layers of the Gibraltar or red Hamburgh made in the beginning of July, reach the length of thirteen feet before the end of the month, yielding at the same time two or three bunches of grapes. The method, when the white muscat is in that space of time, little difficulty is experienced in removing the plants from the pots into the holes prepared for them; if there be fears of preserving a ball of earth to the new roots, the pots may be sunk with them, and then broken and removed; or the plants may be kept in the pots till autumn, when they may very easily be taken out of them without detriment. Macdonald, in his Paper, hence does not state this, as the same way are less durable than those procured by slower means, and where the roots and branches bear a relative proportion to each other. But supposing they were found to be less durable, it is evident that one may thus very easily keep grape-houses constantly stored with healthy fruit-bearing plants, and that the kinds may be changed at pleasure. Then, when they have been trained in the pots, the plants are relieved, and sufficient sun and air admitted, by thus removing two or three shoots; and supposing these to contain each several bunches of some fine sort of grape, they are not lost, but may be ripened, by setting the pots on the side shelves, or flame-trellises, of the pantry, or any hot-house. We have tried this mode with success, and find it greatly aided by ringing the larger at or below the tongue.
2958. Choice by anticipation. A mode of very general utility is to select the plants in the nursery a year before wanted, and to order them to be potted into very large pots, baskets, or tubs, filled with the richest earth, and plunged in a tan-bed. They will thus make shoots, which, the first year after removal to their final destination, will, under ordinary circumstances, produce fruit.

2959. Planting inside or outside the house. Vines are commonly either trained against the back wall, or on a trellis under the glass roof. In the former case, the plants are always placed inside the house; but in the latter, there are two opinions among practical men, one in favor of planting them outside, and the other inside the parapet wall. Where the vines are to be drawn out when in a dormant state, as is generally the case with those trained under the rafters of pineries, there can be no question that outside planting must be adopted; but for pineries, where this practice is not requisite, it seems preferable to plant them inside. This is Nicol's practice, who places one plant "behind the parapet, and between it and the front flue, in the centre of each light."

2960. Mode of planting. Abercrombie says, "Let them be carefully turned out of the pots, reducing the balls a little, and singling out the matted roots. Then place them in the pits, just as deep in the earth as they were before, carefully spreading out the fibres, and filling in with fine sifted earth, or with vegetable mould. Settle all with a little water; and let them have plenty of free air every day, defending them from very severe frost or much wet; which is all the care they will require, till they begin to push young shoots."

2961. Judd's mode of planting seems to be excellent in its kind; it is founded on the principle of increasing the number of mouths or feeders of the roots of plants (746), to enable them to search for, and take up food, rather than gorging such as they may have with too much food, or with food of too rich a quality. The vines being raised from single eyes in March, were in the March of the following year cut down to one eye, and put in bottom best till they produced shoots of sufficient length to draw through the holes in the parapet of his vineyard, or about two feet; afterwards they were hardened in the greenhouse, where a temperature was kept of about 60°, and there they grew two feet more. Holes were opened in the vine border in the beginning of May, and in about a fortnight after, a wheelbarrow full of old tan, or earth of tan, was put in each hole, in the middle of which the roots of the pin-plants remained after being treated as follows: "The leaves were cut off from the lower part of the plant, about two feet and a half of its length; the end of the shoot was then drawn very carefully through the hole, so that the pot being removed, the ball was placed two feet distant from the front of the house, upon its side so that the stem lay in a horizontal position about six inches below the level of the surface of the border. When thus placed, the whole of the stem which was to be covered was slit, or tongued, at each eye, like a carnation layer, by passing a sharp penknife at three quarters of an inch below each eye, and on the side of the eye, about one third of the thickness into the wood, and then upwards to the centre of the joint. This being done, the stem was covered with about four inches of old tan, and the other two inches were filled up with the mound of the border. It is essential to the safety of the shoot, that the slitting be done the last thing, and whilst it is laid in its position, lest the stem should be broken. By slitting the stem, he adds, "a abundance of roots are produced from every eye; the progress of the shoot is not very great until the roots begin to push out;" after which, however, it is so surprising that those under Judd's management were grown from twenty-five to thirty feet in length, and of proportionate strength. (Hort. Trans. iv. 4.)

2962. Season of planting. As the plants are generally in pots, and may be turned out with balls, they may be planted in almost any month in the year; but the autumn or spring months are of course to be preferred. Nicol says, "I have planted grape-houses in May, and in June, that have succeeded so well, as that the plants have reached the top of the house before November in the same years. They were kept in pots, and so carefully turned out of them in transplanting, as that the plants experienced no check, although sprung many inches. I have also done the like with peaches."

2963. Distance. Speechely disapproves of the common practice of planting all the different sorts of grapes at the same distances, and advises a larger or less space to be allowed, in proportion to the natural character and qualities of the plant. Vines planted at three or four feet apart he considers as crowded; for though by this mode a house will soon get furnished, and tolerable crops of grapes be produced in a few years; yet after remaining many years so close together they will be cramped in their growth for want of room, and thereby rendered less productive. On a wall or trellis twelve feet high, he recommends six feet between plant and plant for the weak and delicate kinds, and twelve feet for those that grow robust and strong. But in order to obtain a crop of grapes as soon as possible, he proposes to introduce temporary plants between the principals; such temporary plants to have been grown two or three years, in large pots, so as to come immediately into bearing, and to be trained so as to occupy the upper parts of the wall, while the principals are furnishing the lower. (Treat. on Vine, 102.)

2964. Temporary plants. "At first planting a house," Abercrombie observes, "some of the vines may be introduced as temporary plants. After the wood from a good stool is able to cover the space between two or more lights, plants less vigorous, or which bear fruit not so well approved, may be taken quite away. A vinery is better adapted for cultivating a single plant to a considerable extent than a hot-house."

2965. Pruning and training. The opinions of authors and practical men on this subject are very various; and each, as M'Thill observes, lays "much stress on his own mode;" he adds, "but I am of opinion, that to have good crops of grapes much more depends
on the soil they are planted in, and the climate in which they are kept, than on any methods of pruning or training that have been, or ever can be, adopted.” In this sentiment, every person of observation who has seen a number of the vineyards in this country, or vineyards on the continent, must entirely concur: but as every operation of art is, or ought to be, conducted in a manner suitable to the end in view, it is highly necessary that system should enter into this as into everything else. We shall, therefore, give the various opinions of practical men as to training vines in vineyards, in chronological series, beginning with Speedly, the Moses, as he may be called, of modern British vine-dressers.

2956. Speedly’s mode of pruning and training. Speedly, having planted a vine against a wall or roof-trellis, cuts it down to two eyes or buds (fig. 455. a); the next winter the shoots of the preceding summer are shortened each to one eye (b); two leading shoots are produced, trained upright during summer, and in the following winter headed down to from three to five feet each, and laid in horizontally parallel to the ground, and about a foot above it (c); these main stems produce shoots from every eye, but only a few are selected, which stand from a foot to fifteen inches apart, and these are trained upwards during summer, and in winter every other one is cut out to within two or three eyes of the main stem, and the rest shortened to one third of the length of the trellis (d). The following summer, the third, a moderate crop will be produced from the side shoots of the wood of the preceding year, and from the spurs on the main stem. In the winter following, the shoots which have produced the fruit are shortened down to two eyes, excepting the leaders to the long shoots, which are left with four or five eyes (e). Next summer, the fourth, the top of the roof, or wall, will be reached by the leading shoots, and the spurs are now allowed to produce each one leader. In winter, both of these leaders are headed down to four or five eyes, and the side shoots, from the old wood, to one or two eyes (f). In the following summer, the fifth, a full crop of grapes is produced in every part of the house. This constitutes one course or rotation; and the next, and all the future courses, extend only to four years, in which the object is to renew the upright bearers every fourth year, the intervening spurs furnishing shoots to succeed them. This method is called perpendicular, spur, or Dutch training; but few who adopt it pursue it so regularly as to renew the old upright shoots every fourth year, by which, and for other causes, and chiefly the small quantity of fruit produced during the first four years, it has fallen into disrepute.

2987. Abercrombie’s “methods of pruning established vines” admits of much diversity of method, as the plants are in different situations. Without reckoning the cutting down of young or weak plants, alternately, to the lowermost summer shoot, which is but a temporary course, three different systems of pruning have their advocates.

2989. The first method is applicable only to vines out of doors; but it may be transferred to plants in a vineyard without any capital alteration. In this method, one perpendicular leader is trained from the stem, at the side of which, to the right and left, the ramifications spring. When the plant is established, the immediate bearers, or shoots of the growing season, and the mother bearers, or shoots of the last year’s growth, are thus managed. Soon after the growing season has commenced, such rising shoots as either are in fruit and fit to be retained, or are eligible placed for mother bearers next season, are laid in, either horizontally or with a slight diagonal rise, at something less than a foot distance, measuring from one bearing shoot to the next: the rising shoots, intended to form young wood, should be taken as near the origin of the branch as a good one offers, to allow of cutting away, beyond the adopted lateral, a greater quantity of the branch, as it becomes old wood; the new-sprung laterals, not wanted for one of those two objects, are pinched off. The treatment of those retained, during the rest of the summer, thus differs. As the shoots in bearing extend in growth, they are kept stopped about two eyes beyond the fruit: — the conate shoots,
cultivated merely to enlarge the provision of wood, are divested of embryo bunches, if they show any; but are trained at full length as they advance during the summer, until they reach the allotted bounds: were they stopped in the middle of their growth, it would cause them to throw out troublesome laterals.

In the winter pruning, there will thus be a great choice of mother bearers. That nearest the origin of the former mother bearer, or most commodiously placed, is retained, and the other or others on the same branch is cut away; the branch is also taken off, so that the old wood may terminate with the adopted lateral: the adopted shoot is then shortened to two, three, four, or a greater number of eyes, according to its place on the vine, its own strength, or the strength of the vine. The lower shoots are pruned in the shortest, in order to keep the means of always supplying young wood at the bottom of the tree.

2968. The second method is to head down the natural leader, so as to cause it to throw out two, three, or more principal shoots; these are trained as leading branches; and in the winter pruning are not reduced, unless to shape them to the limits of the house, or unless the plant appears too weak to sustain them at length. Lateral branches from these are cultivated about twelve inches apart, as mother bearers; those in fruit are stopped in summer, and after the fall of the leaf are cut in to one or two eyes. From the appearance of the mother bearers, thus shortened, this has been called spur-pruning.

2969. The third method seems to flow from the second plan as a foundation, in having more than one aspiring leader; and from joining the superstructure of the first system immediately to this, in reserving well placed shoots to come in as bearing-wood. Thus, supposing a stem, which has been headed, to send up four vigorous competing leaders, two are suffered to bear fruit; and two are divested of such buds as break into clusters, and trained to the length of ten, twelve, fifteen feet, or more, for mother bearers next season. In the winter pruning, the leaders which have borne a crop are cut down to within two eyes of the stool, or less, according to the strength of the plant; while the reserved shoots lose no more of their tops than is necessary to adjust them to the trellis.

2971. M'Phail also describes three modes of pruning the vine; the first, or fruit-tree manner, he calls the old method, the general shape of the plant when pruned and trained being like that of a trained peach (fig. 456.); the second he agrees with Abercrombie in calling spur-pruning (fig. 455.); and the third he calls the long or new method (fig. 459.); "though," he adds, "I understand by books (Switzer and The Retired Gardener), that it was in practice nearly one hundred years ago, and I saw it in practice forty years since." It is singular that this old method of M'Phail should have been recently described and figured by a German horticulturist, as a new and "experimentally proved superior method of vine culture;" Versuch einer durch Erfahrung erprobten methode den Weinbau zu verbessern, von J. C. Recht, Berlin, 6vo. 1813.

2972. Forsyth's method of vine training nearly resembles that of Speechly; but instead of laying-in the shoots in a straight direction, either upright or horizontal, he bends and attaches them in a serpentine form (fig. 457.), which has some effect in the open air, or under gentle forcing, of making them break more regularly: though even this is denied by some, who contend that, so treated, they break only at the angles or bends.

2973. Nicol's opinion, as to the different modes of training, is in unison with M'Phail's and our own. He says, "With respect to the manner in which vines should be trained, opinions are on variance. Some advise training the shoots in a straight and direct manner; others in a horizontal manner; and others in a serpentine form. If grapes be otherwise well managed, they will do well in any of the above ways; and I have just to observe, with respect to the last-mentioned method, that it necessarily leads to more confusion, particularly with regard to the training-in of the summer wood, than either of the preceding methods. On dwarf-walls or trellises, the horizontal or zigzag manner of Hitt (fig. 386. g.), or Forsyth (fig. 457.), may be very proper; but in a properly constructed and properly planted grape-house, the most sensible manner of training, in my opinion, is directly up the roof."

2974. The first year after planting, "after the buds have sprung an inch or two, it will be proper to single out those to be trained, and dispose the others with the thumb. Three shoots only should be trained on each plant; that is, the two lowermost, and the uppermost, if it be vigorous; but otherwise dispose it, and train the next below it. As the shoots advance, they should be trained at the distance of ten or twelve inches from each other; allowing them sufficient room in the ties to swell without being bound. Pinch off all laterals as they appear, except one or two nearest to the point of the shoot, lest by any acci-
dent it be broken, and in that case, that a substitute may readily be found; which, however, is never equal to the main shoot; so great care should be taken in the training of principal leaders. One side shoot or two, or even three, shoot out of each main leader, may be stopped when it is five or six feet in length, and the other when, which ten, (as they are to be cut well down in the winter pruning,) which will throw in the more strength to the middle shoots, that are only to be headed down to about six or eight feet, and which, if well ripened, may yield a few fruit next season. These should be encouraged, therefore, and be carefully trained; for the latter will grow.

2975. In the end of the season, say in the month of November, "these shoots," Nicol observes, "are to be pruned thus: the side shoot, stopped first, to three eyes; the other to five or six feet; and the middle shoot, to seven, eight, or ten feet, according to its strength: from which may be expected a good deal of fruit. The shoots from a shoot from the extremity, to be stopped at the top of the house, this time twelvemonth. From the side shoot, pruned to five or six feet, may be expected a few fruit; and from its extremity, a shoot to be headed at this time next year, at nine or ten feet in length, which will, the season following, produce a full cluster of fruit. The second shoots, from the side shoot, shortened to three eyes, are to be expected two shoots; the one to be trained to the height of about nine or ten feet (to be pruned to five or six at this time next year); and the other to four or five only, as it is again to be pruned back to two or three buds this time twelvemonth; thus providing for wood to fill the upper part of the trellis.

2976. If in a process of pruning a shoot is continued on the roof, and the house filled with wood, "there should be," Nicol observes, "three ranges of bearing shoots: viz. one range, at bottom of the trellis, from end to end of the house, reaching from within two feet of the ground, five or six more feet upwards; a second, reaching from a foot, or perhaps two feet under the tops of these, that is, from the ground, to the top of the roof, to the ends of the house, lastly, a third range, from a foot or two under the tops of these last, to the uppermost row of wires or the trellis: the shoots of the first, or lower range, being headed at about five or six feet; those of the second, or middle range, at seven or eight; and those of the third, or uppermost, at about nine or ten feet in length; all a foot or two, more or less, according to circumstances, according to their strengths, how low or how high upon the plants they have issued, and how far they have sprung, and are fully matured. The distance at which these shoots should be placed from each other, in their respective ranges, may be judged by this rule: that, if the shoots of the middle range be fixed twenty inches, in the distance next year, on which the clusters are to hang, as in this season; and which distance may be varied a few inches, according to the kinds of grapes, some growing stronger than others. The utmost shoots on the trellis, or those placed nearest to the ground, and which were only trained to the height of a few feet, must be shortened back to about three feet, perhaps, as they being a principal point in the training of vines, always to provide for a supply of bottom wood, and to keep young wood as near to the ground, or lower parts of the plants, as possible."

2977. Cutting and laying in the shoots. "In pruning, cut generally at two inches above the bud. Some cut nearer, even as near as half an inch, which is apt to weaken the shoot of next season, and sometimes to prevent its vegetating at all; the buds being very susceptible of injury, on account of the soft and spongy nature of the wood. In the cutting out of old wood, be careful to cut in a sloping direction, and to smooth the edges of the wound, in order to prevent its being injured by moisture. The pruning being finished, let the loose, shedded, or hang on the old wood be carefully peeled off, observing not to injure the sound bark, and clear the trellis and branches of leaves, tendrils, &c. Let the shoots and branches be afterwards regularly laid in, at the distances above specified, particularly the young shoots that are expected to bear next season. As to the others, it is not so material; nor is it material in training shoots to the roof, or roof, or branches, for the attachment of fire-heat in the spring. When they are judged to be safe, expose the house night and day."

2979. Hayward's pruning and training. "On the opinion, "that the greater length the sap has to pass through the body of the vine, the more abundant, fine, and highly flavored will the fruit be;" he recommends introducing only one plant in a vineyard, and training it over the whole trellis, either in horizontal shoots from two main leaders (fig. 458. a); or in his wavy manner (b); and he can, as the tree advances in growth, gradually convert the latter into the former mode.

2980. Seton's training. A very scientific mode of training vines under a glass roof, has been adopted at Stanford Hill, by J. Seton, Esq. one of our most enlightened horticulturists, and practised by him for several years with considerable success. It is thus described:—

2981. The vine having, like other trees, a tendency to produce its most vigorous shoots at the extremities of the branches, and particularly so at those which are situated highest, it generally happens, when it is trained, as is most frequently done, across and upwards, from the front to the back of the house, that the greater portion of the fruit is derived from the upper or posterior side of the vine, while the other side, whether the branches be made to consist chiefly of vigorous terminal shoots, preserved at considerable length, or the leading shoots be kept short, and lateral spurs be left for the production of the fruit; but in the latter case, the evil exists in a smaller degree: for the spurs, or short lateral branches, divide the spray. Its main production be meant to the old, or even though they sometimes cross them. Choose straights of fresh matting, or packthread, to tie with; and observe to leave sufficient room for the swelling of the shoots and branches next season, as often already cautioned."
it in a house of small dimensions, I thought I should obviate these inconveniences, in great part, and attain another object, presently to be mentioned, by training the branches in a horizontal direction, and keeping the whole of the fruit-bearing part of each tree nearly on the same level.

The method which I have adopted is that of Dr. Griffith, for this purpose, provided with rods placed horizontally under the girdle of the roof, twenty inches asunder, and extending from end to end. The first vine, placed at one end, being trained up to the two lower rods, a shoot of it was laid along each of them, and continued successively from year to year, till it reached the other end: then the shoots on the two lower rods next, and then the top of each of the tree; while that on the upper rod was turned down, and led back, in like manner, on the lower one. During this process, a sufficient number of spurs, or short branches, was left annually on the old wood, to produce fruit. When the leading shoots, which had been thus trained in a retrograde direction, approached the top of the original branches proceeded, preparation was made for a succession of young wood, bringing forward two fresh shoots from the stem of the tree, and leading them along, close to the preceding ones. As these, and the leading shoots of the first branches, which were then on their third year, were cut down that part of the old wood to which they had reached, were cut out, to make room for them, the naked spur or second spur was left. When the second spur was turned nearly to the end, at which the trunk was situated, the first series, on which there was then but little of the heritage remaining, was cut out at the trunk. Fresh shoots were then brought forward to succeed the second series; and so on without end. It would be superfluous to dwell on the mode of managing the other trees; as it will be perceived that, following the same principle, they must be laid along the higher rods in succession, two rods being allowed to each tree; and when the stem is not at the end of the house, two branches are to be trained eastward, and two westward, along the rod. Thus, in a house of twenty-five feet in length, between fifty and sixty rods, to admit of the length of a branch, as would be the case under the usual mode of training across the house, we have a range of

2982. In the usual mode of management, each tree is under the influence, in its different parts, of all the degrees of temperature in the house; but under the mode now proposed, each tree has its own peculiar climate, to which all alone its parts are exposed. This affords us the command of a most convenient variety, in the temperature, so as for example, to secure the grapes of several varieties, which ripen at different seasons, of the late sorts there will, under the common method, be only a few brought to perfection at the tops of the trees, whilst those that are near the bottom will not ripen, and that part of those trees will accordingly be useless. But in the arrangement above described, and in the training of the same trees, the whole of the branches are laid under the same temperature; by training the early sorts, let us suppose the sweetwater, at the bottom; the middling ones, such as the black Hambro, next; and the late, such as the muscat of Alexandria, at the top. Again, if it be wished to have some very early, and others very late, the order may be reversed, by placing the early varieties at the top, and the late ones at the bottom; in which case the method will be reversed, and the leaves and fruits may be varied in many ways, and will operate under all the degrees of forcing. [Hort. Trans. vol. iii. p. 9, to 13.]

2984. In Griffith’s mode of training and pruning, only a single shoot is led up under each rafter. The vine is planted outside, close to the parapet, and introduced through a hole immediately under the rafter up which it is trained. On planting, it is cut down to one eye; about Christmas, the shoot formed during the preceding summer is cut down to two or three feet; the second year one shoot only is trained from the rafter, forming, at the top of the stem, a shoot of two-thirds of its length, so that, in the third year, the vine will have grown from ten to fifteen feet; and at the Christmas of the third year, the shoot is cut off at the end of the rafter. The spurs are cut down to single eyes every winter, till the main shoots get coarse and rugged, which will happen in about ten years; it is then cut away entirely, a young stem having been previously trained up the two preceding years from the bottom to substitute in its place. As soon as the plants become sufficiently strong to furnish wood, from the point where they enter the house, for a second and third branch, then a proper number must be fixed on as permanent plants, and their side branches brought successively forward and trained to the continuous rafters, “one bearing branch being applied to each rafter, and the plants which originally belonged to these rafter taken away entirely.” The weight of grapes produced by the vine under each rafter by this mode of pruning is generally about forty pounds, two bunches to each shoot, each shoot being about a pound half a pound; and this period is abridged, in the manner affected by the hinged rafters-trellises. (1667.) I also come to, adds this very sensible man in his letter; if these be laid in the same manner as the above, their sides exposed, but as not to occupy the whole space under the glass with the foliage, for I consider that very great advantage arises to the fruit from giving free admission to the sun from the centre of each light. It will be asked by some gardeners, what is done with the leading shoots of the new branches that are cut off? This Griffith answers for his, for his grapes growing three or four joints at the utmost; and these must be cut away, at the time of pruning, down to the old wood, or nearly so; sometimes, to prevent the top of the house being crowded, a little of the old wood at top may be cut off also, and replaced by the next year’s shoot. [Hort. Trans. iv. 104.]
when it has grown three or four joints beyond the middle of the roof, and the weaker after having grown three or four feet, for the purpose of strengthening the eyes. At the fall of the leaf, the leading shoots are reduced, the main one to the length of the middle of the roof (c), and the lower one to the third eye (d). In the third season, one leading shoot is trained in from each shoot (c and d), and from the bearing shoot (e), fruit-bearing side shoots are produced, one bunch is left on each, and the shoot stopped at one or two joints above it: no side shoots are allowed to proceed from the spur (d), the leading shoot from which is to become the bearing wood for the next year. Thus in the autumn of the third season the lower part of the house is furnished with a crop of grapes from shoots proceeding from wood of the preceding year (e), and parallel to this bearing shoot on each vine is the young shoot for next year's crop. In winter, the shoot from the extremity of the bearing branch (e) is cut off at the top of the roof, or within twelve or fifteen inches of it (g), and the shoot (f) from the spur (d) is cut down to the middle of the roof, and all the spurs (on e) which had borne the grapes are now cut out. Each vine is now furnished with two shoots of bearing wood (g, f'), a part of old barren wood (e), and a spur for producing a young shoot the following year (h). In the fourth summer a full crop is produced both in the upper and lower half of the house; the longer shoot bearing on the upper half of its length, and the shorter on its whole length; a leading shoot is produced from the short shoot, and another from the spur. In the pruning season of the fourth year, the centre shoot is entirely removed, and replaced by the side shoot (i), now the whole length of the roof, and this side shoot is in its turn supplanted by the shoot (k) from the spur, while a spur (l) is prepared to succeed it. This constitutes one rotation or period of the system of Mearns, which he has followed since 1806, attended by abundant crops of large-sized bunches; and he considers it may be continued for any length of time. (Hort. Trans. iv. 246.)

2986. In the garden of Marie Leerne, at Ghent, the vines are planted in front, on the outside of the house. Every year a new set of wood is taken into the viney: the wood produced this year, is trained upright on an exterior trellis, and is next season laid down to a sloping trellis, and made to yield its fruit within the house. The wood which has once been forced is cut entirely out, and, from the same roots, new upright shoots are annually required; but unfortunately for the success of this plan these shoots do not always ripen. (Hort. Tour. 62.)

2987. Summer pruning. This depends generally on the necessity of admitting light and air to the fruit and young wood; and particularly on the sort of winter pruning to be adopted. "The gardener, therefore," as Nicol observes, "must have a predestinating eye to the following season." "Whatever methods of pruning are used," M'Phail remarks, "the grape-vine, through the whole course of the growing season, requires constant attendance, so as not to suffer the plant to be crowded in any part with superfluous shoots or leaves, and no more fruit ought to be suffered to swell on the plant than it is well able to bring to perfection. The berries also on each bunch should be thinned, so that they may have room to swell, without pressing too hard upon each other."

2988. Abercrombie and M'Phail agree in directing, that "as the shoots of newly planted vines advance, they must be kept regularly fastened to the rafters. Divest them of their wires, and also take off their laterals as they appear. The vines in general may be permitted to run twenty feet, and the most vigorous thirty-five feet, before they are stopped, if the rafters extend so far. Sometimes a vigorous shoot, having extended the width of the house, is commenced either in the centering direction down a contiguous rafter, or laterally along the top of the stove, as may be most convenient. Stop the shoots by pinching off their tops. After they have been stopped, they usually send out laterals from three or four of the upper eyes. If these laterals are at once taken off, the sap will be merely diverted to the lower part of the shoot; permit them, therefore, to proceed about twelve inches, and then pinch off their tops. These shortened laterals will, in their turn, send out others, which should be stopped at the second joint."

2989. In the second season, "as soon as the shoots are half a span long, the rudiments of the bunches will be perceptible. The bunch is produced on the naked side of the shoot, opposite the leaf-bud. Having ascertainment the most promising shoots, divest the vines of supernumerary branches as they rise. Fruitful laterals will sometimes show two or three bunches at each eye; and this is apt to tempt the pruner to retain too many. On the leading shoot, retain of the best laterals, to the right and left, a number pro
CULTURE in and and "and the but the and the plant the plants shoots reserved on each side the rafter, tying them to the trellis with strands of matting. Leave on each branch two bunches, or a single bunch; according as the plant is in the fourth or third season from its origin; pinch off others. After wards stop the bearing lateral at the second joint above the fruit. Rule, the under-shoot’s, and the older ones inferior the older ones Inferior.”

2990. Nicol observes that most of the summer pruning of vines may be performed with the fingers, without a knife, “the shoots to be displaced being easily rubbed off, and those to be shortened, being brittle, are easily snapped off” or pruned. Thus, the shoots to be removed for the next season, and others necessary for filling the trellis from the bottom, which shoots should generally be laid in at the distance of a foot or fifteen inches from each other, rub off all the others that have no clusters, and shorten those that have at one joint above the uppermost cluster. For this purpose, go over the plant three or four times, and the shoots of the fruit have shown their clusters; at the same time rubbing off any water-shoots that may rise from the old wood.

2991. ‘Train in the shoots to be retained, as they advance; using strands of fresh matting, and allowing sufficient room in the ties for the swelling of the shoots. Likewise pinch off all laterals and tendrils, every time you go over the plant, as these only tend to confusion, and take greatly from the strength of the clusters.

2992. ‘If there be an under trellis, on which to train the summer shoots, they may, when six or eight feet in length, or when the grapes are swelling, be let down to it, that the fruit may enjoy the full air and light, as it advances towards maturity. Such of these shoots as issue from the bottom, and are to be shortened in the winter pruning to a few eyes, merely for the production of wood to fill the trellis, may be stopped when they have grown to the length of four or five feet. Others that are intended to be cut down to about two yards, and which issue at different heights, may be stopped when they have run three yards or ten feet, less or more, according to their strength. And those intended to be cut at, or near to, the top of the house, should be trained a yard or two down the back wall (a trellis being placed against it purposely); or they may be run right on the uppermost trellis, to fill it up. Make a good trainer of vines, and be able to provide for a crop the following season, a man must have some forethought, and be capable of making his selections, as the plants shoot, even at this distance of time. He must predetermine how he shall prune, and where he shall cut, at the proper time, from the plants shoot, so as to push them. He must make himself familiar in his power, with respect to the vine, than any other fruit-tree, on account of its rapid growth and docility.

2993. ‘The stubs, or short shoots, in which the clusters are placed, will probably push again after being stopped, if the plants be vigorous. If so, stop them again and again; but after the fruit is well grown, they will seldom spring. Observe to divest the shoots, in training, of all laterals as they appear, except the uppermost on each; in order to provide against accidents, as hinted at above, in training the new-planted vines. When these shoots are stopped, as directed above, they will push again. Allow the lateral that pushes to run a few joints, and then shorten it back to one; and so on, as it pushes, until it stop entirely. When the proper shoot gets ripened nearly to the top, the whole may be cut back to the originally shortened part, or to one joint above it, if there be reason to fear that the uppermost bud of the proper shoot will start.

2994. ‘Divest the plants of all dammed or decayed leaves, as they appear, as such will sometimes occur in continued hazy weather; and some may be bruised by the glass, in moving the sashes for the admission of air, or by other accidents.

2995. ‘Pruning in the summer prunings, takes off all collaterals as they arise, and any shoots which, though laid in for fruit, turn out unproductive, that the whole strength of the tree may be properly applied. (Hort. Trans. vol. i. 172.)

2996. ‘Mice in his summer pruning stops the bearing branches at the bunch, instead of the next joint above it, which is the usual practice; “for I found that the fruit did equally well, and it divested the branch of an incumbrance, while it allowed a much larger portion of light to come into the house, together with a more free circulation of air among the fruit and young wood. I blind all the eyes on each fruiting shoot, except that of the one, which I retain to draw up the sap to nourish the fruit; I never suffer them to push above a joint or two before I pinch them back, always cautiously retaining an eye, and am particularly careful that nothing should happen to injure the leaf that accompanies the bunch, for if that is lost, the fruit of course will come to nothing.” (Hort. Trans. iv. 255.)

2997. ‘Thinning the leaves and fruit. “Every one of penetration and discernment,” Nicol observes, “will admit the utility of thinning the berries on bunches of grapes, in order that they may have room to swell fully; and further, that of supporting the shoulders of such clusters of the large-growing kinds as hang loosely, and require to be suspended to the trellis or branches, in order to prevent the bad effects of damp or mouldiness in over-moist seasons. Of these, the Hambrough, Lombardy, royal muscadine, raisin, St. Peter’s, Syrian, Tokay, and others, should have their shoulders suspended to the trellis, or to the branches, by strands of fresh matting, when the berries are about the size of garden-peas. At the same time, the clusters should be regularly thinned out, with narrow pointed scissors, to the extent of from a fourth to a third part of the berries. The other close-growing kinds, as the Frontignacs, muscats, &c., should likewise be moderately thinned; observing to thin out the small seedless berries only of the muscadine, sweetwater, and flame-colored Tokay. In this manner, handsome bunches and full-swelled berries may be obtained; but more so, if the clusters on over-burdened plants be also moderately thinned away.” Indeed, cutting off the clusters, to a certain extent, of plants over-loaded and pushing weak wood, is the only means by which to cause them to produce shoots fit to bear fruit next year; and this should be duly attended to, so long as the future welfare of the plants is a matter of importance.”

2998. ‘Remedies for bleeding. “If the pruning has been timely, the vine is not liable to bleed. When the sap rises before the wound is healed, bleeding ensues, and is not easily stopped. This retards the plant; and, out of doors, the loss of a few days is, in some seasons, irreparable; but in other respects, the consequences of bleeding are not so disastrous as many seem to apprehend; and a gardener is sometimes surprised by a subsequent crop of uncommon goodness. Innumerable remedies for bleeding have been proposed: the following rank among the best. Sear the place, and cover it with
melted wax, or with warm pitch spread upon a piece of bladder, or peel off the outside bark to some distance from the place; and then press into the pores of the wood a composition of pounded chalk and tar, mixed to the consistence of putty." (Abercrombie.)

3000. Nicol's remedy. Vines "will bleed in autumn, as well as in spring, though not so copiously at the former season. The best preventive of this is to prune and not pruning till the wood is thoroughly ripe in autumn. Plants that have been pruned too late in the spring, and forced too soon afterwards (a great mistake), will bleed, and the best remedy I know of is tearing the end of the shoots by a hot poker, or rod of iron, in order to dry it, and then to apply hot wax." (Tr. on the Vine, 145.)

3002.-speedy's remedy for bleeding is to peel off or divest that part of the branch adjoining the wound of all the outside bark; then with a sponge dry up the moisture, and immediately wrap round the wounded part a piece of an ox’s bladder, spread over with tar, or pitch made warm, in the manner of a plaster. This is sufficiently tight with it, well rubbed with bees’ wax. These must remain for three weeks or a month. (Tr. on the Vine, 145.)

3003. Knight's remedy consists of four parts of scraped cheese to be added to one part of calcined oyster-shells, or other pure calcareous earth, and this composition pressed strongly into the pores of the wood." (This done," he says, "the sap will instantly cease to flow.)"

3004. Stirring the soil, and culture of the borders. “The borders,” Abercrombie observes, "should be kept at all times clear from weeds. In winter and spring, the surface of an open border should be turned with a three-pronged fork, not digging deep so as to injure the roots. The design is merely to revivify the surface. When it is necessary to recruit the soil, dig the exhausted part carefully up, and work in such a compost as has been described under Soil, or similar. The dung out of a cow-house, perfectly rotted, is a fine manure for the vine." He adds, "From the time the buds rise till the fruit is set, manure the border once in ten days, with the drainings of the dung-hill, poured over the roots of the plants.”

3005. M’Phail recommends digging in rotten dung, and watering with dung-water from the melon-beds; or with that which has run from a dung-hill in a state of fermentation. Forking over, and working a little short dung or compost, if thought necessary, is Nicol’s preparation for the winter. A week or two previously to commencing to force, say about the middle of January (forcing to begin the first of February), he directs the border to be pointed or forked over carefully; and let it be watered over all with the drainings of the dung-hill; which repeat at the end of four or five days, and also again at a flight interval; giving the border this treatment down to the deepest place, and no part shall be overlooked. The border should not be covered, or rather should already have been covered, to a good thickness, with stable-yard dung; not, however, mere litter, but good fresh dung, the juices of which may be washed down to the benefit of the roots. The intention of this covering is to answer as a manure; and also to keep severe frost from the plants. The temperature of the air must be in motion, or the borders will sustain no injury. Previous to laying on the dung, the border should be pointed, or forked over, that the juices may descend more readily to the roots, and not be washed off.

3006. Speedily covered the vine-border in front of his hot-house with gravel; the best gardeners do not crop them at all, or only with the most temporary crops of vegetables.

3007. Time of beginning to force. “The growing season of our climate,” Abercrombie remarks, “does not last long enough to bring out, swell to full size, and perfectly ripen, the fruit and summer shoots of the vine. Hence, when the artificial excitement, applied to this plant, begins just before the natural spring, and is continued till the leaves fall, the plant is beneficially assisted under a deficient climate rather than forced. The best time to begin to force is the first of March, if the object be simply to obtain grapes in perfection moderately early. In proportion as the start is accelerated before this, the habits of a deciduous plant, and the adverse state of the weather, leave a greater number of obstacles and discouraging contingencies to intercept final success. Managers, however, who work a number of houses, and who have to provide, as well as they can, against demands for grapes in early succession, begin to force about the 21st of December, and, successively, in other houses, the 1st of January, 1st of February, and so on. Attempts are even made, by bold speculators, to lay forward for a crop in March, by beginning to force in August, and getting the fruit set before November: but such labor and expense is often lost. The period of ripening is not early in proportion to the time of beginning: when the course of forcing coincides nearly with the natural growing season, ripe grapes may be cut in five months or less; when short days compose a third part of the course, in about six months; when the course includes full half the winter, it will last nearly seven months.”

3008. M’Phail, in case grapes be not wanted very early, considers the month of February the best time to begin the forcing, the subterranean potity, the young leaves on the vine, being in their first expansion, and the earliest crop of grapes was over by the end of June, and the grapes laid aside, or left open on the house day and night, you may, if it is desired to try to have grapes early in the spring, prune your vines in the hot-house, and the heat, the light, and the wind, will be sufficient to set the buds to work; and if it is necessary to dig in manure about the roots and stems of the vines, let it be done. If your border be dry, give it a good soaking, and if with drainage also, at this time, it will help to enrich it. When this is done, draw on your glasses, and keep the air in the house to a moderate degree of heat, and your vines will afterwards shoot out, and if they are in a fit state for this treatment, you will not have plenty of vines in other houses to succeed these, it would not be advisable to begin to force at this season of the year, for there are several things that might reasonably be urged against the probability of the success of this attempt to ripen grapes early in the spring; but it may succeed, and therefore, it is worth giving it a trial. By custom, the vines can be well forced, as it were naturally, and shoot forth in the autumn, and their fruit may be set before the shortest days; the greatest art will then, after that, be to preserve them through the dead winter in
a lively growing state. This can be done only with much attention, in making gentle fires, and admitting an easy circulation of fresh air in the house every favorable opportunity."

3009. *Nicoll* says, "Those who have two or three grape-houses, generally begin to force the earliest by the last week in February, or December."

3010. In Holland, *Speechly* observes, "they begin to force the vines in November, in order to have ripe grapes in April, and sometimes they succeed in producing them by the end of March, in pretty good condition."

3011. *Griffin* puts on the sashes and commences forcing early in January; no fire is used the first week; in the second week a little fire is made every other night; the third week the heat is kept from 500 to 520, but not allowed to exceed 530 till the vines begin to break; from that time, until they blow, the heat may be raised to 570 and 580; and whilst they are in bloom the heat is raised to between 570 and 630. "Air is regularly given plentifully through all these stages, until the bloom appears, when the heat is kept close, except the sun be very powerful. When the bloom is past, attention is paid to thinning the grapes, a regular heat is then kept up, and air in due quantity, as the weather permits."

3012. Care of outside stems. "At whatever season forcing commences, the vines of plants outside the house should be guarded from the stagnating effects of cold, by a bandage of hay, or moss and bass matting, round the hole, and a mulch of dry litter over the root. The excluded stems must be protected in the same way at the commencement of the forcing season. While the vines are young, it will also be advisable to cover the outside border, in winter, with strawy dung taken from the outside of old hot-beds." *(Abercrombie.)*

3013. *Griffin* keeps the stems of his vines inside the house moist, from the time of beginning to force till the beginning of spring, and sometimes, by day, water them with a syringe. This, he says, contributes materially to the production of vigorous shoots. Some gardeners wrap the stems round with moss, which they keep moist for two or three months, for the same purpose. In hard forcing, practices of this sort are particularly necessary.

3014. Temperature. "Begin," *Abercrombie* says, "at 50° min. 55° max. In a week, raise the minimum to 55°, and the maximum to 60°. Till the time of budding, the temperature should not exceed 60° from artificial heat, and 64° from collected sun-heat. After the buds are in full motion, it may be raised to 60° min. 64° max. from fire, and 68° from sun-heat. By the time the bloom expands, the lowest effect from the flues should be 66°: the highest may be 72°; and when the sun's influence is strong, let it be accumulated, by confining the interchange of air to the ventilators, till the heat rise to 80°. After the fruit is set, the minimum should be 75°, and fresh air copiously admitted."

3015. *M'Phail* says, in beginning and continuing to force the vine, "nature should be imitated, by increasing the heat as the days lengthen; but it should be remembered, that to ripen the best sorts of grapes, they require as great a heat as the pine-apple does to ripen it in the summer; for the vine has no artificial heat to its roots."

3016. *Nicoll's directions*, supposing the forcing to commence on the first of February, are as follow: "Make the fires so moderate as that the thermometer may not pass 50°, or at most 55°, mornings and evenings, until every bud in the house have begun to spring. This is a point of very great importance in the forcing of vines, for the sphagnum, or the green, if raised to between, and if a high temperature be kept up from the beginning, the chance is, that a third or fourth part of the buds will not push, and of course there will be a great falling off in the expected crop. After the whole of the buds have blown, and an even vegetation, they must be raised to between 69°, 65°, and 70°, at which it may continue till the bloom begin to open. This rise from 50° to 70° must not be sudden: it should not be effected in less time than a fortnight; or, if the plants be not in a very strong state, three weeks, otherwise the shoots will push weakly." After the plants come into bloom, he directs the heat to be raised to 70°; *M'Phail* and *Abercrombie* allow it to be a little higher, "with the sun heat, and if there be air at the house. When the fruits are ripening, the air of the house ought to rise from 75° to 85°, with sun-heat and plenty of air." *(Pr. Gr.)*

3017. *Meares*, in forcing the vine, considers it of the utmost importance to the bold breaking of the buds, and to the strength of the wood, not to force vines hard, until the first leaves arrive nearly at their full size. "After that period," he says, "I give them a much less portion of air, suffering the sun to raise the thermometer to 80° or 100° before I give any. There is no danger of drawing the wood after that stage of growth, and if the thermometer sinks at night to 60°, the vines will do better in a higher temperature in the day." *(Hort. Trans. iv. 254.)*

3018. *Air.* *Abercrombie* directs this to be given pretty freely by the sashes till the leaves unfold. Before the foliage is fully made out, begin to keep the house close, admitting air only by the ventilators; and particularly observe to have a sultry, moist climate while the blossom is coming out, and until it is off and the fruit set. While the fruit is swelling and ripening, the plants will want abundance of heat and air." *(Pr. Gr. 651.)*

3019. *M'Phail* recommends a little air to be given during a part of the day while the thermometer is above 65°, and the sun shines in the winter months, and abundance in the summer season when the heat exceeds 80°.

3020. *Nicoll*, in beginning to force, admits air freely every day, by opening the sashes in the ordinary way, until the foliage begins to expand; and to an extent that the thermometer may not rise to more than five degrees above the fire-heat medium in sunshine; but thus bringing away the buds strong and vigorous. But after the foliage begins to expand, except in fine weather, the house should be chiefly aired by means of the ventilators, until the blossom is over, and the fruit begin to set; or at least until the season become mild.

3021. When grapes are setting, air need not be admitted so freely as before, grapes being found to set best in a high heat. "A moderate circulation by the ventilators will be sufficient for the purpose, except perhaps in clear sunshine; when it may be necessary to open a few of the sashes at top, in order to let the rarefied air escape, and keep the temperature within due bounds. Air is to be increased as the season and growth of the plants and fruit advance. When the fruit is ripening, it should be admitted more freely than here-
tore in order to give the fruit flavor; for on this, and on the withholding of water, as advised above, that matter entire depends." (Kalm.)

3022. An application for vines is strongly recommended by Williams (Hort. Trans. i.), because in it "the wood, though of slower growth, is more compact, and the fruit more saccharine. Hence vines growing on the sides of mountains in the south of Europe, and in the dry warm province of La Mancha in Spain, yield richer grapes, and make stronger wines, than in the vineyards bordering on water, where, however, they experience more water warmth, and the fruit arrives sooner at maturity. From the beginning of July till the middle of October, he generally leaves several of the upper lights of his vineyard open about two or three inches all night."

3023. **Watering and steaming.** Abercrombie says, vines require a plentiful supply of water from the time the fruit is well set till it begins to color, particularly when the berries become transparent at the last swelling. Withhold water entirely when the grapes approach maturity.

3024. M'Phailt says, "If the vines be planted in the inside of the house, care should be taken to keep them sufficiently watered, and in dry weather, in the spring and summer, the border in the outside of the house should be kept wet by a constant supply of water. The plants should get their supply of water and fruit clean, let the plants be watered occasionally with clean water, thrown on them by a tin squirt or eauine, but take care that the decaying paint on the rafters be not washed down on the leaves and fruit, which would stain and harm them. Should there be any danger of that, it will answer the purpose well by filling the house full of steam now and then, by sprinkling water on the flues when they are warm." Alluding to the first stage of early forcing, the same author observes: "In some houses, the border, or part of the border in which the vine is planted, is in the inside of the house; where that is the case, let it be watered and sprinkled now and then to keep it in a moist state. Water the flues sometimes when they are hot, which will produce a fine steam, very beneficial to the plants in promoting their growth, and in preventing them from being infected by the red spider. Steam, however, should not be used too copiously. If the border for the vines be in the house, or if there be plenty of plants in pots of earth in it, the evaporation of moist earth is generally sufficient to moisten the air properly; and besides, there is a continual draught of external air coming into the house among the plants; and it is known that the common atmosphere contains moisture at all times, especially in cold weather, when the ground is full of rain."

In March, vines, when kept in the house and sprinkled, will be as well and thrive as much as those kept in the open air, while having been driven from the borders of the house by the force of the water. If the paths, flues, and borders in the house be sprinkled and watered occasionally as I have directed, grape-vines will do without giving them water over their leaves and fruit, at this season of the year; though I by no means disapprove of washing them well, now and then, all over, leaves and fruit, provided it be done with clean water, and no filth driven on them from any part of the house. From the time that grapes are swelled to a size that you can hardly perceive them to grow larger, till the black sorts begin to change color, and the white ones to appear of a more bright color than at first, their swelling is generally a growth by their skin, which, being swallowed in the growth of the fruit, is then with clean water. The border outside the house may, probably, in the summer months, require a good watering now then. (G. Icm.)

3025. Next, after the commencement of forcing, "has the border duly and frequently referred to water, generally at least three or four times daily, and if occasionally watered with the drainage of the drains, it would add much to the vigor of the plants. The branches should be watered once in two days by the engine, with a considerable degree of force, in order to keep the plants clean, and prevent the breeding of the red spider and thrips, which are often very troublesome in the grape-house." As vines advance in growth, "they must be liberally supplied with water. The vine, when in a free-growing state, requires more water than is generally imagined; and many, very many gardeners, half ruin their plants, and very much injure their crops of fruit by withholding this element. I know some who do not give as much water to a vineyard in the state of forcing or ripening, as they do to their washing and before their grape leaves have become dirty, and before the grape-house is on the move. When the fruit is ripe, the leaves are large, as wheat-straw, and berries the size of garden-peas!" Increase the supplies of water with the advances of the season and growth of the plants. "As the fruit begin to color and swell off for ripening, the quantity of water, hitherto liberally given, must be lessened by degrees; and, towards its coming to full maturity, must be entirely withdrawn, lest it be no longersince the occasion may be slight; and besides, it is not the occasion, but the necessity, that is the cause; but previously, be particularly severe, and be careful to scourge it well, that no vestige of the red spider be left. This is a matter of very great importance, and but little attended to; and for want of taking this care, the more they have then, and hence soon a whole crop of grapes very much spoiled, and the berries rendered dirty, nauseous, and bitter."

3026. **Ripening the wood.** Abercrombie directs, "If the fruit be not off by the middle of August, the continuation of fine dry weather, or of the heat dependent on the natural climate, will hardly be sufficient to ripen the wood; and therefore, as soon as the external air declines to 60°, resume gentle fires, morning and evening, so as to keep the minimum temperature of the house to 70°. The maximum need not exceed 75° in sunshine; for fresh air should circulate at every proper opportunity. Proceed thus until the shoots of the season have ceased to grow, and turn brownish at bottom, and the leaves begin to fall, indications that the wood is ripe, when the first and last are not caused by a deficiency of heat."

He adds, "If the weather continues warm after the fruit is cut, take off the glass frames; as the shoots will ripen the better under full exposure to it. In October, however, it will be advisable again to put on the frames, as well by shelter to assist the ripening of the wood, if that is not complete, as to protect the house from injury, when rough wintry weather may be expected."

3027. Nicols says, "If the lower part of the shoots be not, by the beginning of August, turning brownish, then it is advisable to apply a little fire-heat, in order to further the growth of the plants, and the perfection of the fruit; some would put them out of the way another month; but if the application of fire-heat be at all necessary, less trouble and expense for fuel will attend the temperature of ripening the wood in September than in October. Another consideration is, that, as it were, you take up vegetation on the way, and hand her forward to the end of her journey, instead of allowing her to lag behind, and then forcibly push her on against her inclinations; a matter of the very first consideration and importance in every species of horticulture. Let very moderate fires be made at first, increasing their strength as the season advances, and so as to keep the temperature, mornings and evenings, at about 70°. This should be continued till the growth of the plants begin to stop, and till the part of the leading shoots whereat you would
cut, that is, about six or eight feet upwards, become brownish. The portions of air, hitherto freely ad- mitted, must be lessened by degrees, as the weather turns cooler; and so as that, in sunshine, the mercury may not fall below 35°. When the growth of the plants is over, expose the house day and night, except in rain. Water must also be withheld, as the growth of the plants abates, and somewhat in the proportion in which you would have vegetation stop; not all at once, but gradually. Continue the operations of the en- gr. 400. g, f. gineer, and which, not merely to subdue the enemy at present, but, as far as possible, to prevent his ap- pearance next campaign."

3028. Exposure and resting of the wood. "Some managers," Abercrombie observes, "leave the house quite exposed when the vines have done growing; and whether it be covered or not, there should be constantly a circulation of air through it. Vines which have been exposed to the weather, or freely to the dry air, in a state of rest, when forced after a proper interval, generally break at almost every eye." The rest proper to a de- ciduous plant cannot be given to vines where the branches are kept subject to the influ- ence of a permanent heat after the leaves are fallen, as in the case of vines grown in pine or other stoves. The top of its stem, with its branches, must therefore be withdrawn from the house immediately after the fall of the leaf, to remain on the outside till it be proper again to force the plant. Abercrombie says, "the branches will require no covering in this climate," but many gardeners lay them down, or tie them to stakes, and cover them with litter or mats.

3029. M'Phail says, "Some modern writers on gardening recommend that the glass frames of the grape-house be taken off the vines as soon as the vines are all cut; and also to take the vine-plants out of hot-houses and apprize the culture of the pine-apple when the grapes are over. This they tell us is to ri- pen the wood, and give the plants rest, &c. I do advise that the glass frames of grape-houses be suffered to remain over the vines all the year, excepting in July and August, and that grape-vines in hot-houses for ornament be either taken out for the winter, or remain for any length of time at any season of the year. If fruit-trees ripen their fruit well, the wood for bearing the following year will be sufficiently matured; but the plants, whether they be the grape-vine, peach, &c. had best remain in that artificial climate made for them all the year, for though the fruit be over, the wood of the plant requires protection. As well," he adds, "might we expect the cherry-tree to blossom in September and October; which months are some years warmer than the month of April, when the cherry-tree is in full blow, or that the Christmas- rose may be excited by summer heat to blossom in July or August. It is natural for the grape-vine to produce only one crop in the year; and when it is accustomed to grow in a hot-house appropriated for the pine-apple, its nature is not changed; nor will it offer to put forth its bud before January in hot-houses kept to a heat sufficient for growing the pine-apple, when the pine pots are plunged in a bed of warm tan."

3030. Knight, as we have seen (218.), is highly favorable to putting the vine into a state of repose, as early as possible in the autumn preceding the season in which it is to be forced.

3031. Nicol, after the growing season, and when the wood is ripened, "exposes the house day and night, except in rain." After an autumn pruning, he shuts up the house for ten days or a fortnight, particu- larly if there be no appearance of frost; admitting air freely through the day. The object in thus keeping the plants from the extremes of heat and cold, is, in or- der that their pores may contract, and their wounds heal gradually; as otherwise they are apt to bleed now, and to break out a fresh on the application of fire-heat in the spring. When they are judged to be safe, expose the house night and day, as before. (Kal. 429.)

3032. S. Galton describes a plan of exposing the branches of vines growing in a stove to the external air, without the necessity of suspending the forcing oven or heat in the stove, or of drawing the stems back through apertures by which they are introduced into the house. This was put in practice at Derby, in the garden of Joseph Strutt, of that town, where it has been in suc- cessful use, for above fifteen years. The foundation wall in front of the house is capped with a stone sill (fig. 460. a); the front upright lights (c) move on centres pins, and can be taken out from their places without disturbing the rafter plate (b), or the uprights which support the plate; these lights, when taken out, can be fixed by the lower ends to the inner side of the stone sill, the spaces of the uprights being filled by other pieces, whilst the tops are held by a board (d) longitudinally fixed to the rafter by hinges (e), and capable of being raised and let down at pleasure. When the vines are ripened, they are unfastened from their places between the rafters, and laid down on the stone sill (a); the front upright lights (b) are then taken out and fixed on the inner side of the sill (f), thus leaving the whole of the vine on the out- side of the house, and under cover, protected from rain, until it is desired to put it again into heat, when the situation of the upright lights is changed, and they are replaced in their former situation. (Hort. Trans. iv. 367.)

**Subsect. 2. Of particular Modes of cultivating the Grape, adapted to particular Situations.**

3033. The particular modes of cultivating the grape which we shall now enumerate, re- fer to its culture in pineries, green-houses, and other plant structures, by dung-heat, in hot-bed frames, temporary frames and glass covers, hand-glasses, and cultivating for re- tarding maturation.

3034. Forcing the vine in a pine or other stove. Abercrombie, in a comparison between the hot-house or general stove and vineyard, justly observes, that the former "has many cir- cumstances of inferiority to the vineyard; and, although its shades of inconvenience or in-
perfect accommodation are not weigh'ty enough to forbid the dedication of any spare room to the vine, yet they are sufficient to confer very great credit on the manager who obtains a good crop of fine-flavored grapes under them. (Pr. G. 657.)

3035. Speedily, even the vine may be advantageously grown together; but subsequent experience having led to the culture of pines in pits, most gardeners, and among these Nicol, prefer growing them in the open air.

3036. M'Phail, without being to a decided approbation of their union, gives the following directions on the subject, which are to be taken in connection with his opinion as given above, on the improbability of withdrawing the wood to rest it in the open air. To manage the grape in a hot-house appropriated for growing its own fruits, and for treating its own fruit, the following method must be observed: In the month of November or December, cut down all the old wood to about the height of the pit, leaving only two young shoots, the strongest that can be got, to cut short and to grow long shoots to bear the fruit. To the other shoots, the little one that is to be cut short and to grow long shoots to bear the fruit. This is to be done successively at the end of the first year, leaving the young shoots the vine to grow, as the older the plant is the better. After the vines are pruned, tie them up nearly close to the glass, with matting, to iron rods or laths fixed to the rafters of the house. As soon as they begin to swell in their buds and show themselves ready to break, let them be covered with the leaves from the bottom of the earth; and then they are free from their cover, and not be liable to be affected by the frosts. If the buds burst strong and bushy, it is a good sign that they will show fruit; but if weak, the contrary; and, if they miss showing fruit on the fourth or fifth joint, they will show none at all; and in that case the young shoot that does not show fruit should be cut off, and the wood worked in the same manner from the old shoots which have shown fruit. Do not let more than one or two bunches grow on one bud, for if too many are left on the plant, they will not swell well. If the vines be planted in the inside of the house, care should be taken to keep them sufficiently watered; and in dry weather, let the ripening and summer buds, that border on the sides of the house, in which the roots of the vines run, should get plentiful waterings. In order to keep the leaves and fruit clean, let the plants be washed occasionally with clean water, thrown upon them by a tin sprinkle engine, but take care that the decaying paint on the rafters be not washed down on the leaves and fruit, which would stain and hurt them; and if any danger of that, it will be answered by increasing the water as well by filling the house full of steam now and then, by sprinkling water on the flues when they are warm.

3037. Growing grapes in green-houses and other houses. Vines are grown under the rafters in green-houses, conservatories, and in most kinds of forcing and other hot-houses; but, as the gardener who undertakes to raise plants in such buildings very likely, in any case of that sort, we do not consider it necessary to introduce here any thing farther on the subject. The excellence of the fruit, and the grateful nature of the plant, than which none is more certain of rewarding the gardener's care by abundant crops, will, we trust, justify our having brought together the practice of so many cultivators.

3038. Forcing vines by dung-heat. Justice, Lawrence, and Switzer state instances of this being done on wooden walls in their time. Fletcher, a market-gardener near Edinburgh, has practised it with great success in a glass case, keeping constantly, till the fruit is about to ripen, a heap of dung, or dung and weeds, in a state of fermentation in the area of the house. But the most systematic and extensive forcing of this kind is that which has for fifteen years been practised by J. French, Esq., a gentleman farmer of East Hornden, in Essex, and which has been thus described by a late intelligent fellow of the Horticultural Society.

3039. French's mode of forcing vines by dung-heat. About the beginning of March, French commences his forcing, by introducing a quantity of new long dung, taken from under the cow-crisis in his straw-yard, being principally, if not entirely, cow-dung, which is laid upon the floor of his house (fig. 461.), extending entirely from end to end, and in width about six or seven times, leaving only a path-way between it and the back wall of the house. The dung being then at the beginning of the month, the steam ariseth with the first heat, which, in this stage of the process, is found to be beneficial in destroying the ova of insects, as well as transfixing a worm or two of the smallest degree of that, it will do no more unless it is injurious, if permitted to rise in so great a quantity when the leaves have pushed forth. In a few days the violence of the steam abates as the buds open, and in the course of a fortnight the heat begins to diminish; it then becomes necessary to carry in a small addition of fresh dung, laying it in the bottom, and covering it over with the old dung fresh forked up this produces a renovating heat and a moderate exhalation of moist vapor. In this manner the heat is kept up throughout the season, the new dung being constantly laid at the bottom in order to smother the steam, or rather to moderate the quantity of exhalation; for it must always be remembered, that French attaches great virtue to the supply of a reasonable portion of the vapor. The quantity of new dung to be introduced at each turning, must be regulated by the greater or smaller degree of heat that is found in the house; the season or other circumstances appear to require it. The temperature kept up is pretty regular, being from 65 to 70 degrees. French contends, that the moist vapor which is transfixed through the house is essentially beneficial, not only in destroying the discouers of insects, and destroys their ova, but it likewise facilitates the setting and swelling of the fruit. I ought to observe, that I am not offering any opinion of my own in the present statement, but merely recording, as faithfully as possible, the remarks made to me by a person of ingenuity and observation, whose extraordinary success is, in my mind, the best test that can be given of the merits of his practice. (Andover, in Hort. Trans. vol. i.)

3040. Meatsna "approves greatly of applying the steam and heat of dung to the forcing of grapes, and uses it in the earliest part of forcing with great advantage, forming a large ridge of it in the back part of his house, and introducing the additions of recent litter always under the old dung." (Hort. Trans. iv. p. 256.)

3041. Advantages of using dung-heat. The practice of applying the heat of horse-dung, and of other fermenting substances, to the forcing of vines and the growing of pines and other plants, usually excited or prevented by their inherent heat in the nature of fire-heat, is claimed ever since very significant advantage, that the ammoniacal and carbonic gas, which is disengaged during the decomposition of the dung, is highly injurious to insects, while to vines before the buds protrude themselves, and to pine-plants at most seasons, it is found not at all injurious. These things known, every farmer might have an excellent vineyard attached to his farm with sufficient profit, and the steam and heat, thus obtained, might be turned to every advantage, in meeting the various occasions of the season. A few apertures along the upper part of the house being kept at all times open, there could hardly occur any injurious accumulation of steam, and the same openings would render daily attention in giving air unnecessary; for there is abundant experience to prove that a vineyard in which the apertures for admitting air at bottom and top are opened in spring, may be left with them in that state night and day till autumn, without the smallest injury. All that the farmer would have to do,
would be to water the plants two or three times a week with a syringe or engine, and to tie up the shoots, as they grew, to the trellis. As in this way the enjoyment of a numerous class of men might be increased at very little expense and labor, we intreat the attention of head gardeners and proprietors to the subject, as calculated, like the dissemination of every other rational luxury, to be conducive to the general good. Opulent, or proprietor farmers, who have extensive farmeries, and probably two or three separate strawyards (fig. 432. a and b) might raise all the fruits grown in first-rate gardens by the same means, and add not a little even to the elegant appearance of their establishments. A pinery, for example, might be formed over a large dung-bed, and the side walls, being hollow, like those of Silverlock (Hort. Trans. iv. 544. and fig. 228.), or of West (Hort. Trans. iv. 230. and our fig. 530.), would preserve the air within perfectly pure, so as to admit the growth even of ornamental trees, &c. The additional expense of management to the farmer, in this case, would be chiefly the difference between keeping a half-bred gardener and a common laborer.

3042. Forcing the vine in hot-bed frames, and other glass cases. Knight, after describing his inclined hot-bed and frame, and its advantages in respect to cucumbers and melons, adds, "I have often used, with great success, a frame and hot-bed thus formed, for forcing grapes, by placing the bed at three feet distance from the wall, to which the vines were trained, and introducing their branches into the frame, through holes made at the north end of it (the vines having been trained to a south wall), as soon as the first violent heat of the bed had subsided. The white Chasselas grape, thus treated, ripens in July, if the branches of the vine be introduced in the end of April; and a most abundant crop may be thus obtained; but the necessity of pruning very closely renders the branches which have been forced unproductive of fruit in the succeeding season; and others from the wall must consequently be substituted. I have always put a small quantity of mould in the frame, and covered it with tiles. If an inclined plane of earth be substituted for the hot-bed, and vines be trained in a frame adapted to it, the grapes (the Chasselas) ripen perfectly in August; and if small holes be made through the sides of the frame, through which the young shoots of the vines can extend themselves in the open air, a single plant, and a frame of moderate size, will be found to yield annually a very considerable weight of grapes. For this purpose, the frames should not be more than eight or ten feet long, nor more than five or six in breadth, or the young shoots will not be so advantageously conducted out of them into the open air; and the depth of the frame, either for the hot-bed or inclined plane of the earth, should not be less than eighteen inches. The holes in the side of the frame, through which the young shoots are to pass, should of course be closed during the spring, and till wanted; and if the weather be cold, it will be necessary to cover the frames at night. When the grapes are nearly full-grown, and begin to ripen, it will also be highly advantageous to draw off the glasses during the day, in fine weather, by which means the fruit will be exposed to the full influence of the sun, without the intervention of the glass, and will attain a degree of perfection that it rarely acquires in the vineyard or hot-house."

3043. Mean, gardener to Sir A. Hume, has practised a mode very similar to that of Knight, for a number of years; and, as such simple modes of obtaining early or well ripened grapes are within the reach of every one who has a grape-vine trained against a wall or house, we shall quote his account of it. "This method is particularly applicable in cases where vines are trained to walls, and do not ripen their fruit, nor bear well. The frame must be high enough in the sides, to admit of the vines being trained horizontally on a trellis, to keep the pendant bunches clear of the dung, and to give free room for the leaves below on the vine branches and the glass. The frames used at Wormleybury have either one or two lights; the latter are nine feet long and six feet wide; the fronts of the frames are eighteen inches high, and the backs are two feet high; the trellis is fixed nine inches from the glass, which gives sufficient space above and below. The upper board at the back of the frame, being nine inches wide, lies up or slides off; so that the branches are laid in without suffering the injury they would sustain in their buds, if they were drawn through holes. In the first or second week in April, just before the vines begin to move, you make up acommon dung hot-bed at a convenient distance from the wall, or from the place where the shoots of the vines will fall. In this bed you put a layer of dung on the bottom, and then two inches of fine earth, and the top-dressing should be used, if the frame is so placed as not to be exposed to the sun; but if it be exposed, it is not necessary to include the use of a frame. In this bed you put the bunches of grapes, and then cover them with earth. The soil must be warm, and the proper temperature maintained. In this way, a good crop of grapes is sure to be obtained; and if the frame is so adapted as to be exposed to the sun, it will be necessary to open the arches when the sun reaches it. The fruit will ripen, and produce an abundant crop; and it is found, that the ripening of the fruit is accelerated, by laying slates or tiles over the dung. At the end of the season, those shoots which have borne their crop are cut entirely away, and a fresh supply introduced of young shoots, which have been making and ripening their wood on the wall; these are treated in the same manner, the wall annually yielding a successive supply of young wood to be taken into the frame." (Hort. Trans. ii. 230.)

3044. Temporary frames and glass cases have been constructed by Lindegaard, Tel-bron, and various gardeners, foreign as well as British, but more especially those of Holland and Flanders, against walls of vines. Sometimes a temporary furnace and flue is built, and at other times a dung-bed is resorted to, and very excellent crops are obtained.

3045. Ripening grapes under hand-glasses. About twenty years ago, a market-gardener at Bath published a plan of ripening grapes under common hand-glasses. He planted the vines in a soil composed in great part of lime rubbish; placed a glass over each plant, taking out half a pane in its summit, through which the leading shoot of the
vines protruded itself, and grew in the open air. The bunch or bunches of grapes remained within the hand-glass, and enjoyed the advantages of protection from cold winds, dews, and rains, during night, and of a high degree of confined solar heat during the day.

3046. Forcing vines in pots. This is not a very common practice, because the vine requires a greater extent of pasturage for the roots than any other fruit-tree. It has, however, been occasionally attempted by gardeners in pits and stoves, and three or four bunches are sometimes thus obtained from one plant. The soil must be as rich as possible, and every attention paid to keeping the plants regularly supplied with water and liquid manure. Knight employed water impregnated with pigeons' dung to the color of porter, and found, in consequence, the most vigorous growth. He states, that a pot containing two cubic feet of very rich mould, properly supplied with water and manure in a liquid state, is fully adequate to nourish a vine, which, after being pruned in autumn, occupies twenty square feet of the roof of a hot-house. Such vines he constantly found to produce more vigorous wood when forced very early, than others of the same variety, whose roots were permitted to extend beyond the limits of the house. (Hort. Trans. vol. ii. 373.)

3047. Marsland, of Woodbank, near Stockport, has a succession of grapes during eleven months in the year. This is the pot in which the vines are allowed to remain and replaced by others; the plants are from one to four years old, and at the latter age they bear abundantly, and produce large bunches. (Hort. Trans. vol. ii. 575.)

3048. Buck finds this method of obtaining grapes answer particularly well, and by removing the pots in the winter months, when the fruit is full ripe, into a dry airy situation, he can preserve it for the table much longer than he can in the vineyard, when cloudy and damp weather prevails. (Hort. Trans. vol. iv. 561.)

3049. Cultivating for retarding maturation, so as to obtain a supply in the winter season, is thus described in the Transactions of the Horticultural Society, as practised by Arkwright, of Willersley.

The sorts cultivated for this late crop are the white muscat of Alexandria, the black Damascus, the black Tenerife, the St. Peter's, the black raisin, the Syrian, and the white Nice. They are grown in houses alternately used as pineries and vineeries. About the second week in February, the pine-plants are always removed into another viney. The grapes which remain on the vines are all cut, and the house thrown open for the free admission of air at all times, till the end of April, when the vine-buds begin to swell, when a gentle fire is applied in the night, and in dark and cold days; but air is admitted freely when the thermometer is at 70°. At this period, a proportion of the pine-plants is again brought into the house, and remain till the succeeding February. The treatment from this time is quite in the common way; and by this late and slow process, the grapes do not begin to ripen till towards the end of October, and the very late sorts, such as the St. Peter's, are scarcely ripe at Christmas. The following note is added to this paper by the secretary:

Specimens of grapes ripened in this manner were exhibited by Arkwright to the society on the 5th of February, 1819, and were as rich, perfect, and fresh, as if they had been produced at the usual season: and the leaves of the vine, which were sent at the same time, were in an undiminished state of vegetation. These leaves, Arkwright has since stated, were from the late sorts of vines, viz. the Syrian, the Nice, and the St. Peter's; those of more early kinds, such as the muscat and the Damascus, begin to assume their yellow tinge about Christmas, but their fruit continues quite fresh and good for a considerable time afterwards. The conclusion is obvious, that the vines made to produce these late grapes had acquired the habit of late bearing, and this habit, Arkwright states, has been brought on gradually. Whenever he introduces a young vine into the house, where his late grapes are grown, it is treated exactly like the vines which are in bearing, and in the second or third year after planting, when it begins to yield fruit, it is found to have lost its disposition to break into leaf at the accustomed season. Arkwright began to produce a batch of grapes about two months earlier, and at that time they are ripe, and therefore are forced into the early grapes; and so successful was his plan of retardation, that, on the 1st of May, 1810, he had on his table fresh-gathered fruit, the produce of two years, viz. of the late crop of the past, and the early crop of the present year. He has now ceased to force any vines for early fruit, and confines his cultivation to that of late grapes alone.

Subsect. 3. Of Gathering and Keeping Forced Grapes.

3050. With respect to the gathering of grapes, Nicol observes, "they should be allowed to hang till fully matured and ripened; especially the thick-skinned and fleshy sorts. Even the thin-skinned and juicy kinds, as the white sweetwater, white Frontignac, and muscadine (that are often cut before nearly ripe,) are much improved in flavor, by being allowed to remain on the plant till the skin become transparent, and of a russet or yellowish color." The grapyery, when the fruit is ripe, ought to be kept dry and cool in order to preserve the fruit as long as possible on the branches, and thus to prolong the grape season. Covering the border an inch or two with dry sand, ashes, or gravel, Nicol says, contributes to dry the air and dispel damp. The leaves round the bunches are to be picked off for the same end, and a fire to be made in the day-time in gloomy weather.

3051. Thompson, gardener to Earl Cowper, at Panshanger, preserves grapes in his vineyard till February, by lighting fires in the day-time, and giving plenty of air; but putting them out in the afternoon, and shutting the house close up at night. "The fire in the day, aided by the circulation of the air, renders the whole house perfectly free from damp, so that no condensation can take place. If, on the contrary, with the houses closed, creates a vapor, which causes the fruit to become mouldy, and to decay. The sorts used were the Frontignacs, sweetwater, and black Damascus." (Hort. Trans. vol. iv. 139.)

3052. McPhail observes, "there are some sorts of grapes, such as the black muscat of Jerusalem, the Syrian, Tokay, and some others, which will keep on the tree a long time after they are ripe, provided the house be kept dry and cool."
3055. Various modes for drying the air in a grapery. Decayed granite or trap, which has been discovered by Professor Leslie to be powerful absorbents of moisture, where they can be obtained, would be excellent substitutes for ashes; or oatmeal might be used (being swept up and dried occasionally), were the harboring of vermin not to be dreaded. (See Supp. Encyc. Brit. art. Cold.)

3057. Grapes may be kept by packing them in jars, "every bunch being first wrapped up in soft paper, and covering every layer with bran, which should be well dried before it is used; laying a little of it in the bottom of the jar, then a layer of grapes, and so on, a layer of bran and of grapes alternately, till you have filled the jar; then shake it gently, and fill it to the top with bran, laying some paper over it, and covering the top with a bladder tied firmly on to exclude the air; then put on the top or cover of the jar, observing that it fits as close as possible. These jars should be kept in a room where you can have a fire in wet or damp weather." (Tr. on Fr. Tr.)

SUBSECT. 4. Of the Insects and Diseases attendant on forced or Hot-house Grapes. 3058. The insects and diseases of the vine are not numerous: of the latter there are few or none, unless bleeding may be excepted, the remedies for which we have already given. (2999.) The insects which infest the vine, are chiefly the red spider and coccus. To remove these, Speechly and Abercrombie recommend washing the stem and all the shoots with soap and water; the stem being previously divested of the loose bark. Abercrombie adds, give the border two or three soakings over the roots with soap-suds. If the plants get infested with the pine-bug or turtle insect, it is to be extirpated by syringing the leaves with a strong infusion of tobacco-stalks. Watering is the best preventive of the red spider, and aphis or green fly, and fumigation keeps down, and in part destroys the latter and the thrips.

3059. M'Phail observes, that the red spider, the mealy white bug, and the brown turtle insect are the most injurious to the vine. "These insects lodge upon the wood of the trees, and upon their leaves, and upon their fruit. To prevent accidental infection, care should be taken not to introduce infested plants into the house; keeping the air in the house among the plants sweet, and to a strong degree of heat, with constant admission of fresh air, are good preventives against insects. To help to destroy insects on the vine, peel off, in the autumn, winter, or spring, before the plants begin to grow, all the loose outside bark, and wash, with soap-water mixed with sulphur, the stem and all the branches, rubbing them well with a sponge or brush, which will destroy the insects, and the spawn of them that have been deposited thereon. If they happen to be infested very much, after they are well washed with clean water, let the stem and all the branches be smeared with a mixture of sulphur, soot, and water, put upon them with a painter's brush." Rotten and decayed berries or leaves are to be removed, that they may not spread their infection.

3060. Nicot considers the red spider as the grand enemy to the vine. After every winter pruning and removal of the outward rind on the old wood, he directs to anoint the branches, shoots, and trellis, with the following composition, the object of which is the destruction of their eggs or larvae.

[recipe for a substance to control pests]

3062. Birds, wasps, flies, &c. several gardeners direct to be excluded by gauze frames, calculated to fit the openings by which air is given. Some recommend putting bags of gauze over each bunch; others hang up bottles, boiled carrots, &c. M'Phail says, "Fix nets on the parts of the house where you admit air, and fix them in such a way as that the sashes will slide backwards and forwards either in the outside or inside of the nets. The net should be as thick in the meshes as that a wasp cannot fly through them." It may be noted, that a flying wasp (the wings being distended) will not require meshes smaller than an inch square.
PRACTICE GARDENING. Part III.

SECTION III. Culture of the Peach-house.

3063. Soil. Abercrombie recommends three parts of mellow unexhausted loam, and one part of drift-sand moderately enriched with vegetable mould, or the colder dungh. The border or bed to be thirty inches or three feet deep. The nectarine wants the warmer, richer, and deeper soil, if any difference be made. (Pr. G. 292.)

3064. M'Phail recommends the soil for peach-trees which are to be forced, to be “fine loamy well-prepared earth of medium texture, neither very light, nor of a strong binding quality, well mixed with some good manure. The border to be four feet deep, and so broad, that the roots cannot get into a bad soil.” (Gr. Rem. 18.)

3065. Nicol. The bottom being made “comfortable by draining and paving, if not naturally dry, directs the breadth of the border to be the width of the house within, and to the extent of ten or twelve feet without. The average depth thirty inches at the least; but if a yard, it would not be too much. The soil to be thus composed: three fourths strong loam, an eighth part light sandy earth, and an eighth part rotten stable-yard dung, with a competent quantity of lime and marl; all being properly mixed before planting.” (Kal. p. 291.)

3065. Blanagan, for peaches and nectarines, whether in houses or on open walls, uses "the top-slip of a pasture of rich yellow loam, if it can be procured, without adding to it any manure whatever; if poor and sandy soil, a little rotten stable-yard dung, and the whole should be laid up on ridges, and turned over for six months previously to using.” (Hort. Trans. vol. v. 57.)

3067. Choice of sorts. The following list is given by Abercrombie as the most proper for forcing:

PEACHES.

Cling Stones.
Portugal. End Sept.
Golden. Sept.
Catharine. Early in Oct.

Free Stones.
White nutme. End of July.
Large Magdalen. Mid. Sept.
Belle China. Late in Aug.
White Magdalen. End Aug.
Montaban. End Aug.

Chancellor. End Aug.
Malt. Early in Sept.
Royal George. Mid. Sept.
Le Teton de Venus. Late in Sept.
Late purple. Late in Sept.

NECTARINES.

Cling Stones.
Red Roman. Late in Aug.
Newington. End Aug.

Golden. Sept.
Brugnion. Late in Sept.

Free Stones.
Scarlet. End of Aug.
Murray. Early in Sept.

Temple. Sept.

3068. M'Phail says, "The names of peach-trees fit for forcing are the Magdalen, Montauban, royal George, and noblesse; of nectarines, the scarlet, temple, Murray, and red Roman." (G. Rem. p. 18.)

3069. Nicol recommends the following:

PEACHES.

Red Magdalen.
White Magdalen.

NECTARINES.

Elurgen | Duc de Tello | Scarlet | Murray | Temple | Roman | Newington; and | Brugnion.

3070. Choice of plants. "Before a house for forcing peaches and nectarines be built," M'Phail observes, "trees to plant in it had best be got in readiness; and if they be growing on the premises it will be an advantage. If it can be avoided, no tree should be planted in a forcing-house until the fruit of it have been seen and tasted. The trees should be well trained ones, four or five feet high; indeed it is of no consequence what their age be, provided they be healthy, well rooted, and in a bearing state: and if they have been transplanted several times since they were budded, they will be the fitter for transplanting again; and if the work of taking them up and of planting them in the peach-house be carefully and methodically done, the trees by their removal will be but little retarded in their growth. When every thing in a forcing-house is got in readiness for the reception of the trees, loose them from the wall to which they were fastened with nails and shreds, and dig a wide semicircular trench four feet distant from the stem of each tree, and a little deeper than their spreading roots; then by little and little with a pointed stick work the earth out among their roots, taking care to break as few of them as possible: in this manner the roots of the plants are to be divested of earth in a careful manner, so as to undermine the stem, that the tree may be lifted out of its place without straining the roots of it. Having holes previously prepared about eight or ten inches deep, and four feet wide, set the trees into them one after another, training their roots out in a regular horizontal manner at full length, and after the ends of the roots be cut so as to take the raggedness off, cover them no deeper than about six inches at their extremities, and at the stem of the tree about four inches."

3071. Nicol prefers clean, healthy dwarfs, that have been one or two years trained, to older plants; and riders three or even four years trained; because, being temporary, it is desirable to have produced fruit as soon as possible, for if the dwarfs thrive, the former will have to be removed in three, or at most, in four years. In a house thirty-five feet long, three dwarfs should be planted, and in a house thirty-five or forty feet long, four dwarfs; in both cases with riders between them. (Kal. p. 233.)

3072. P. Flanagan prefers plants that have been grown in stiff loam and three years trained.

3073. Situation of the plants in the house. Permanent occupants, intended to be forced early, Abercrombie plants in a front border, training them on a trellis just under the roof. In late forcing-houses, he trains them to an upright trellis near the back wall.

3074. M'Phail plants so as to train under the glass; and Nicol's practice concurs with that recommended by Abercrombie.
3075. For late peach-house, dwarfs should be planted in front, to be trained about half way up the roof; and dwarfs, with riders between them, against the back wall, to be trained to the top. In this case, the trees on the back wall would be in front, and the trees in front would be nearer to the back wall half way up the sloping glass; and thus the greatest possible extent of unshaded surface, and the greatest quantity of unshaded fruit may be obtained. A house planted in this manner, about forty or forty-five feet in length, may have four dwarfs in front, and four dwarfs and five riders at back; and the length of the house might be forty-five feet, which would produce a large quantity of nectarines and peaches. If only thirty or thirty-five feet in length, three dwarfs in front, and three dwarfs and four riders at back, would be trees enough to fill it. (Pract. Gard.)

3076. For an early peach-house many consider the plants as safer when trained against the back wall, or on a trellis not nearer the glass than three feet. This is the Dutch practice, and was that of Speechly, and Kyle, of Morendon.

3077. Season of Planting. Abercrombie recommends November and December as preferable; or otherwise February and March: M'Phall, “any time when the weather is open, between October and March,” which practice is also agreeable to that of Nicol. Plananag plants in the latter end of autumn, or beginning of spring, placing a compost of three parts loam and one of dung immediately round the roots, in order to encourage the plants to strike more freely into the general soil of the border. (Hort. Trans. v. 58.)

3078. Training. All seem agreed in recommending fan-training for peaches and nectarines; which being the simplest and most natural of all training, we deem it unnecessary to quote opinions at length.

3079. Pruning. This, according to Abercrombie, may be performed at the fall of the leaf; but should be completed before the blossom-buds are considerably advanced. M'Phall says, the best season is the spring, when the blossom-buds can be distinguished.

3080. Nicol, in the case of a newly planted house, heads down the maiden plants, or cuts in the trained trees, about the end of March or beginning of April. “With respect to the dwarfs, the shoots of the older branches are cut back to two or three buds, that the trellis may be furnished from the bottom with young wood. The shoots on the upper or farther extended branches may be shortened back to half, or one third of their lengths, according to their strength, provided they have been well ripened, and are free from canker; but if the tree be anywise diseased, let them be cut so far back as to get rid of the canker-stock. If the matter of precaution, it would rather advise that no diseased tree be planted, unless of a particular kind, that cannot be easily obtained. The riders need not be headed so much in as the dwarfs; the object being rather to throw them into a bearing state, than to cause them to push very strong shoots, which would not be fruitful. If they make moderately strong shoots, and may be thinned for bearing, they may be trained in the same manner as the dwarfs. The young shoots may be laid in, as they advance, at the distance of about nine inches from each other; this is, of the dwarfs. Those of the riders may be laid in considerably closer, it not being intended they shall grow as strong as those of the dwarfs.

3081. Planagan says, “If the trees appear to make luxuriant shoots in any part where bearing wood is wanted, the shoots should be stopped at the third or fourth leaf, and if they are still inclined to grow strong, they must be stopped a second time; this will obtain kindy wood. Two or three times in the fall, if it can be obtained, the shoots should be thinned by leaving those which are most kind and well placed at regular distances for the next year’s bearing. The first thinning of the young shoots should be just after the fruit is set, and when they are eight or ten inches long; when at that length, they must be laid in at such distances as to admit the sun and air to ripen the wood. This is the principal business of the first season; since to the young wood regularly laid in, to attend to the top and bottom waterings, and to the free admission of air at all times. If all this has been done, and the plants have been kept clean, they will in this season have made plenty of good bearing wood for the next year, and they will have nearly covered half the extent of the house. (Hort. Trans. v. 29.)

3082. The winter pruning. In a bearing-house is supposed to take place in November; and if the summer shoots have been regularly trained, and laid in at the distances of nine inches in the dwarfs, and rather nearer in the riders, they will not require much pruning at this time. A few of the shoots may be shortened back; the thinner and middle parts of the tree, for the purpose of providing a supply of young wood in these parts, and thinning out such shoots here and there as have been left too thick; for others should not be shortened, but should be laid in at full length; that is, such as are short, stout, nearly of an equal thickness, and have a bold wood-bud at the extremity; as from these may be expected the best fruit next season. “In some parts of the tree, perhaps, or in some particular trees, it may be expedient to cut out such old branches as have but few young shoots on them, provided there be neighboring branches better furnished, whose shoots may be spread out, so as to fill, or nearly to fill, the vacancy occasioned by such lopping. In this case, the shoots, borrowed, as it were for this purpose, must be shortened more or less, according to the size of the vacancy to be filled up, and according to their strengths, in order that the plant may appear complete in all parts as soon as possible.”

3083. The summer pruning consists in pinching off all fore-right shoots as they appear, and all such as are placed at the bottom of the tree by luxuriance, and throw out those branches. “If they are not shortened, and the leader and the shoots shall be let alone, there will be formed a crop lost, one conveniently placed strong shoot is shortened in June to a few eyes, in order that it may throw out laterals.

3084. The fruit is thinned after the stoning season, as already described in treating of thinning of wall-fruit. (2570.)

3085. Abercrombie says, “There should be a preparatory thinning before the time of stoning, and a final thinning afterwards, because most plants, especially such as have overborne themselves, drop many fruit at this crisis. Finish the thinning with great regularity, leaving those retained at proper distances, three, five, or five, on strong shoots; two or three on middling, and one or two on the weaker shoots perhaps, never leaving more than one from the same eye. The fruit on weakly trees thin more in proportion.”

3086. Nicol concurs with these remarks. “If,” he says, “the trees set an immoderate quantity of fruit, which plants do in a healthy and strong condition, such will too often fall off; it is then, better to cut off early. The fruit on weakly trees in a more vigorous condition should be thinned; thinning most where health is most wanting, and least where it prevails over sickness. And observe, that for want of timely and judicious thinning, the fruit in some cases is often very thick, and too much, which will from the very first be lost. The fruit on strong trees in a bearing-house in a state of bearing, when the fruit is swelling off, in order that it may attain a greater degree of perfection, such leaves and summer shoots as overhang and shade the fruit are taken off or thinned.”
3087. Fall of the leaves of forced peach-trees. Nicol says, the leaves of peach-trees "may be dressed off," when the wood is ripened, by the use of a withe or small cane, which is more necessary in a house than if the trees were growing in the open air, where the wind or frost might make them tumble down fast.

3088. Stirring the soil. The borders are to be pointed and forked up after pruning, and a little well rotted dung or compost added where deemed necessary. The part of the borders on the outside may, in addition, be covered with dung; and after forcing is commenced, those in the inside may be occasionally watered with the drainings of the dunghill. (Kal. 324. 438.)

3089. Time of beginning to force. "From the rise of the sap," according to Abercrombie, "it occupies, in some sorts, about four months to make mature fruit; in the later varieties, five months; and when much of winter is included in the course of forcing, the time is proportionally lengthened. To ripen moderately early kinds by the end of May, begin to force on the 21st of December. Little is gained by commencing sooner. But you may put on the glasses a week before, and make gentle fires, admitting a constant stream of fresh air, to get the house ready."

3090. M'Phail says, "Those who wish to have peaches and nectarines ripe in May, should begin to force them about the beginning or middle of December." For a general crop, Nicol, Weeks, and most gardeners, recommend forcing to begin the month of February. Nicol offers "a word to the novice in forcing: Be diligent, and drive too slow rather than too fast. Most new beginners in this business make haste to outdo, or to eclipse their neighbours; and so drive on at a pace they cannot long keep up, but founder their steed, and stop short by the way."

3091. Temperature. Abercrombie directs to "begin at 42° min. 45° max. from sun-heat; and rise in a fortnight to 45° min. 50° max. from sun-heat, giving plenty of air; in the progress of the second fortnight, augment the temperature from three to eight degrees, so as to have it at the close up to 53° min. 56° max. from sun-heat, admitting air in some degree daily. When the trees are in blossom, let the minimum heat be 55° min. 60° max. Continue to aim at this till the fruit is set and swelling. When the fruit is set, raise the minimum to 60°, the artificial maximum to 65°, in order to give fresh air: when the sun shines, do not let the maximum, from collected heat, pass 70°, rather employing the opportunity to admit a free circulation of air."

3092. M'Phail, beginning in February, keeps the thermometer to about 55°, increasing it as the days lengthen; when set and swelling, raise it to 60° with fire-heat; when the sun shines, let it rise to 65° or 70° with air. A short time before the fruit begins to ripen, from 65° to 70° is not too much, with fire-heat, and in sunshine days a little above 75°.

3093. Flanagan begins to force a new-planted house in the second week of February, by putting on the lights, and begins fire-heat at the end of the month. The second season he puts on the lights in the latter end of January. (Hort. Trans. v. 58. 59.)

3094. Nicol, in a house begun to force on the 1st of February, begins with 45° for the first fortnight, and then increases the heat to 50° or 52°. The times of regulation are supposed to be at six or seven in the morning, and at eight or nine at night. At the end of a month the temperature is to be kept as steadily as possible to 55°. In two months, keep it to about 65°, seldom allowing it to pass 70°, which, if it does, it will have the effect of drawing the shoots up weak, and may cause the setting fruit to drop. He recommends 60° by fire-heat, mornings and evenings, as proper after the fruit is fairly stoned.

3095. Flanagan, the first season of forcing a peach-house, "attains a temperature of from 59° to 59° from fire the last week of February, and does not allow the sun-heat to exceed 65°. The second season of forcing, fires are made in the second week of February, just to keep the heat by fire from 45° to 50°, not exceeding 70° of sun-heat; in the third week the fire-heat is gradually increased from 50° to 55°, and not exceeding 75°, with sunshine, particular attention must be paid to the regularity of heat, which may be progressively increased a degree or two as the season advances, but I do not allow it to exceed the last-named temperature until the fruit is perfectly stoned, when I increase it from 55° to 60° at night, and from 77° to 60° of sun-heat. At the medium of these the temperature should continue during the remaining part of the season." (Hort. Trans. v. 60.)

3096. Air. A constant stream of fresh air is to be admitted before beginning to force, and plenty of air during sunshine throughout the whole progress of forcing. M'Phail says, when the fruit is set and swelling, "give the house air every day, whether the sun shine or not." Give plenty of air, and keep the house dry, when the fruit begins to ripen. When the intention is to begin to force on the 1st of February, Nicol shuts up the house from the middle of January, admitting plenty of free air through the day. During the first month of forcing, he admits air freely "every day, even in frosty weather, by the sashes, till the flowers begin to expand; after which time by the ventilators, except in fresh weather, till the season become mild. Air should be admitted all this month, to such an extent as to keep down the temperature, in sunshine, to within five degrees of the fire-heat medium; and this in order to strengthen the buds as they break, and that the young shoots may spring in a vigorous manner." Admit large portions of air every day when the fruit is swelling off, except in damp weather, from seven or eight in the morning to five or six in the evening; opening the sashes to their fullest extent from ten till two or three o'clock, giving and reducing gradually, &c.

3097. Watering and steaming. "While the fruit is in blossom," Abercrombie observes, "steaming the flues must be substituted for watering over the herb; at the same time, you may water the roots now and then gently, avoiding such a copious supply as might risk the dropping of the fruit to be set. Let the water be warmed to the air of the house."
3998. M'Phail directs to keep the border moist by watering; and after the fruit are as big as nuts, sprinkle the flowers now and then with water to raise steam, and wash the trees about once a week with clean water, but too cold in it. It is well to water all over the top till the fruit begins to ripen. A sunshine morning is to be preferred, and the water may be about 60°. Do not water after the fruit begin to ripen, but re-commence when all are gathered. (Gard. Rem. 148, 151.)

3989. Nicol says, "newly planted peach-trees should be freely supplied with water at the root throughout the season, to prevent their sprouting, and the engine must be applied with force to the branches, for the suppression of the red spider, and refreshing the foliage, generally once in two or three days." In a fruit-bearing house, after the fruit is set, "water should be given pretty freely to the plants at root, once in a week and more, as long as they bear fruit and before the fruit begins to ripen. Also, continue the operations of the engine regularly; and do not be sparing, or be afraid to hurt the foliage, if the red spider appear on it. Hit hardest of, or near to the top of the house; as it is there he prevails, being fostered by the extreme heat, in which he delights. In looking out for this enemy, therefore, pay more attention to the borders of weak trees, and then effectually do not water near the border, and cease to exercise the engine on the foliage when the fruit is swelling off." (Kal. 508, 601.)

3100. Flanagan, whilst the trees are in bloom, neither sprinkles nor steams the house, for he "considers that sufficient moisture arises from the earth in the house at this stage of forcing." (Hort. Trans. v. 60.) While the fruit is forming, he once or twice in the morning steams the earth, and waters the borders in the house occasionally after the stoning, until the fruit is arrived at full size, and begins to change color, then all watering should be left off both with the syringe and on the borders.

3101. Insects and diseases. The red spider is the grand enemy to peach-trees; but they are also attacked by blight, mildew, the aphis, thrips, and sometimes even the coccus. "The blight," Abercrombie says, "is caused by small insects, very pernicious both to the trees and fruit in their growth; this is apparent by the leaves curling up, and often by the ends of the shoots being bunched and clammy, which retards their shooting. In this case, it is advisable to pick off the infected leaves, and cut away the distempered part of the shoots. Further to check the mischief, if the weather be hot and dry, give the trees a smart watering all over the branches. A garden-engine will perform the watering much more effectually than a common watering-pot, as it discharges the water in a full stream against the trees. Apply it two or three times a week; the best time of the day is the afternoon, when the power of the sun is declining. These waterings will clear the leaves, branches, and fruit, from any contracted foulness; refresh and revive the whole considerably; and conduct greatly to exterminate the vermin."

3102. M'Phail directs, when the plants have begun to expand their blossoms and leaves, and the aphis, or green insect, makes its appearance, to fill the house full of tobacco-smoke once a week, or oftener. If there be any appearance of mildew, dust a little sulphur on the infected parts; and if the gum or canker be seen on the trunk, never cut it off, but let it stand,-there is not any use in cutting off the branches every part minutely, and if you perceive the dark dying, or the gum oozing out of any part of them, cut off the bark as far as it is dead or decaying; and if the branches be strong, that you cannot well effect it with your knife, take a chisel with a semicircular edge, and a mallet, and cut out the wood as far as you see it is affected; you need not be afraid of hurting the tree, even if the branches or main stem be cut half away. I have cut sometimes more than half of the stems of standard trees away from the ground farther up than where the branches began to separate, which was the means of saving them alive. This method exposes the wood to the sun, and air, by which it is dried, and the tree is thereby assisted in casting off the unwholesome juices, or those kept in it too long for want of a more dry, genial climate. (Gard. Rem. 161.)

3103. Mitchel, of Montcrieff House, Perthshire, hangs on his peach-trees, when the fruit are ripe, "large white glass phials, with a little jam or jelly in them, in order to entice large black flies, which he finds very destructive to peaches. Wasps he destroys by finding out their nests in the day, marking them with a stick or bayonet, and setting fire to the wood, which produces a burning stick, saturated with wet gunpowder, which stupefies the wasps. He then pours water over them, and with a spade works up the nest, earth, and water, into a sort of mortar. Nests on trees or hedges he stipples with the wet gunpowder, which makes a white appearance, which he considers a very drastic method." (Caled. Hort. Trans. v. 104.)

3104. Nicol strongly recommends watering for keeping down insects, especially the red spider. If the green fly or thrips make their appearance, recourse must be had to fumigation. Shut the house close up at night, and fill it to full of tobacco-smoke that one person cannot see another. If this should be repeated the next evening, they will be completely destroyed. Calm weather is most favorable for this operation.

3105. Nicol and Abercrombie recommend that in November, when the winter pruning is finished, the peach-trees should be covered with the compost recommended for vines.

3106. Ripening the fruit. Knight finds that neither peaches nor nectarines acquire perfection either in richness or in flavor, unless they are exposed to the full influence of the sun during their last swelling, without the intervention of the glass. In consequence, he says, some gardeners take off the lights wholly before the fruit begins to ripen; but he recommends taking them off only in bright sunshine, and putting them on during rain, and at night to protect the fruit from dew, &c. "When the fruit begins to ripen, which will be about the second week in July, I gradually expose the house to the open air on fine and dry days, by drawing down the lights as much as convenient in the day, and shutting them again in the evening. It is this which gives the fruit both flavor and color." (Hort. Trans. v. 61.)

3107. Gathering the fruit. M'Phail advises laying moss or some soft material over the borders, to save those which drop off of themselves. Nicol recommends the peach-gatherer. (fig. 148.) Sir Joseph Banks, quoting from a French author, states that "Peaches are never eaten in perfection, if suffered to ripen on the tree; they should be gathered just before they are quite soft, and kept at least twenty-four hours in..."
the fruit-chamber." (Hort. Trans. vol. i. App.) Williams, of Pilmaston, says, "Should the season prove wet when the peaches are ripe, they should be gathered, and placed for about two days in a dry airy room before they are eaten." (Hort. Trans. vol. ii. p. 113.)

3108. Ripening the wood. Abercrombie says, "On account of the fruit of most sorts of peaches ripening somewhat earlier than grapes, and the growth of the shoots stopping sooner than the summer-wood of vines, it is not so often necessary to assist the plant, in September or October, by artificial heat; but in some of the late kinds, if, by the time the external air is down to 60 degrees, the shoots have not taken a greenish-brown tint as high as several eyes from the origin, and if the blossom-buds on these, round when full swelled, are not distinguishable from the oblong wood-buds, apply a little fire-heat, and continue it till the leaves fall."

3109. Nicol directs attention to be had to the ripening of the wood of peach-trees in September. A little fire-heat may be necessary fully to mature the shoots, especially of young trees. "Fire-heat should be continued till the growth of the smaller and middle-sized shoots stop, their bottom parts become greenish-brown, and the buds upon them, that is, the flower-buds, appear turgid, and be distinguishable from the wood-buds. The stronger and more extreme shoots of the dwarfs in particular will continue to grow later than the above shoots; which, as they are to be considerably shortened back in November, for the production of wood to fill the trellis next season, is not very material, provided the bottom part be pretty well hardened."

3110. Resting the wood. The management of the peach-house, when at rest, Abercrombie says, "Should be nearly the same as for the grape-house, except when there is but one set of frames to serve both an early peach-house and late grape-house; in which case, as soon as the young wood of the vines is perfectly ripened, the glasses should be brought back to the peach-house; for although the fruit of the grape is to be set and ripened in a higher heat, the peach-tree, as a plant, is more tender than the vine; and independently of forcing, comes into blossom about two months sooner."

3111. McPhail keeps on the glasses from the time the fruit is gathered till he begins to force, in order to keep the wood dry; but gives them all the air he can. (Gard. Remem. 367.)

3112. Nicol exposes the house fully day and night, only shutting up in the time of heavy rains. (Kat. 490.)

3113. Forcing peaches and nectarines by dund-heat. The following mode is practised at Dagnam Park: — "The house is seventy feet long by eleven feet wide, the front wall being five feet and a half deep from the bottom of the lights, the depth from the roof (there being no upright lights in front) to the ground: about three feet and a half of the bottom of this wall in open brick-work, with a flue in the inside, the top of which is covered with plain tiles. The inside of the house is filled up with earth to within two feet of the bottom of the lights, and the trees planted as near as possible to the front wall, and trained under the lights or wires, in the same way as vines. The back wall of a pine-pit is built of the same height as the front of the peach-house, and three feet distant from it; this of course forms a space three feet wide for the hot dung. As soon as I wish to begin forcing, this space is filled with hot dung: the roots being near the flue, soon begin to feel the warmth, and I sometimes take off a few tiles from the top of the flue, so as to admit the steam from the hot dung into the house; I find this of great advantage, and productive of no ill effects, until the leaf-bud begins to expand, and if the stream is not then perfectly sweet and moderate, the places left to admit it must be secured. You will of course observe, that while this hot dung lining is forcing the peaches and nectarines, it is assisting to work the pines in the pine-pit at the same time, and without any additional expense, there being also a lining at the front of the pine-pit, as well as this one at the back; and when it has become cooled by frequent turnings, I either make cucumber-beds of it, or take it inside the peach-house or vinery. For these five years past, I have never failed in producing an abundant crop of peaches and nectarines by the above method." (Breese, in Hort. Trans. v. 219.)

3114. Forcing the peach-tree in pots. "All the varieties of the peach and nectarine," Abercrombie observes, "are extremely well suited for forcing in large pots or tubs. Small plants, intended to come in before or after those in the borders, may be excited, in the first stage, in a distinct house; so as the temperature of that in which they are brought to finish fruiting be suited to their progress. The compost for plants in cradles ought to be lighter and richer than the mould in the borders." The pots or tubs should be such as not to contain less than a cubic foot of earth; the soil should be lighter and richer than that recommended for the borders, and liquid manure should be plentifully supplied, to make up, in some degree, for the confinement of the roots. They are best forced in a peach-house, but succeed in a vinery or succession-stove; best of all, however, in a pot or Dutch frame (fig. 446.), where the temperature can be regulated at pleasure, and where they are near the glass. Great care must be taken to supply them regularly with water, for which purpose some place saucers under the pots; others cover their surface with moss, or, what is better, fresh cow or rotten horse dung. Casing the pots with ropes made of moss, is also a very good method, as it not only preserves a uni-
form degree of moisture, but also of temperature. Of course the moss must be kept watered. Peach-trees, in pots, are sometimes trained to small fan-trellises attached to the pot; but in general they are pruned as dwarf-standards, in which form they bear fully better than when trained. When the fruit is nearly ripe, the pots ought to be removed from the hot-house or vineyard to a cooler and more airy situation; or, if in pits, the sashes may be taken off a part of every fine day. In other respects, the treatment of peach-trees in pots is similar to that of trees in borders.

3115. Williams, of Pilmaston, observes, that in respect to the quality of fruit from peach-trees in pots, “by far the best-flavored peaches I have ever tasted, were from trees planted in large pots, and kept in a vineyard from February till the first week in June; when the trees were removed into the open air, and after being shaded a little from the sun for the first ten days, were placed in the most open part of the garden till the fruit became ripe. Treated in this way, the peach becomes beautifully colored on the outside, and of a most exquisite flavor.” Occasionally, in very warm seasons, peach-trees in pots, when forced very early in the season, and afterwards plunged in the open air, will produce a second crop late in autumn; but this is more matter of curiosity than of utility. It frequently happens with forced cherries and strawberries. (Hort. Trans. iii. 367.)

3116. Peach-trees as standards. The peach bears remarkably well in the standard form, planted in the middle of a house; and the flavor of the fruit is universally acknowledged to be preferable to that grown on the trellis, from the comparatively free circulation of air. The glass tent, or moveable house (fig. 226.), might be most advantageously applied in this way; and when the fruit began to ripen, the sashes could be removed, and applied to ripening a late crop of grapes against a common wall, or to cover pits or houses which had not been forced.

Sect. IV. Of the Culture of the Cherry-house.

3117. No fruit is more difficult to force than the cherry. The blossoms of forced trees are apt to fall off before the fruit is set, and the fruit will keep falling off before and after they are as large as peas. This is thought to be occasioned by a kind of stagnation of air about them, which affects the tender blossoms and young fruit.

3118. Soil. M'Phail says, “Take light, sandy, rich, mellow earth, and make a border of it the whole width of the house, and four feet deep.” Nicol — “The border should be from twenty-four to thirty inches deep; the bottom, if not naturally mild and dry, to be drained and paved. The soil should be a sandy loam, or light hale garden-earth, made moderately rich with stable-yard dung well reduced, or with other light compost. If a small portion of lime, or a moderate quantity of marl were mixed with it, so much the better. The soil for cherries to be forced in pots or tubs, should be considerably richer than the above.” Torbron uses fresh virgin soil and rotten dung. (Hort. Trans. iv. 116.)

3119. Choice of sorts. M'Phail, Nicol, and all gardeners, agree in giving the preference to the May-duke. Nicol says, “None of the other kinds set so well, except the Morella, which I do not hesitate to say well deserves a place: it is a good bearer, and the fruit, when forced, acquires a superior size and flavor.” (Kal. 295.)

3120. Choice of plants. M'Phail takes standards of different heights in a bearing state; Nicol, clean, healthy, young plants, that have been one or two years in training against a wall. Torbron trees, eight or ten years from the bud, and selected of such various heights as best suited the size of the house.

3121. Situation of the plants in the house. M'Phail and Torbron plant in rows, beginning with the tallest in the back side, reserving the shortest for the front, letting them slope to the south gradually, somewhat in the form in which plants are set in the greenhouse. (G. Rem. 146.; Hort. Trans. iv. 116.)

3122. Nicol has a trellis against the back wall for wall-trained trees, and a border in front, in which he plants dwarf-standards. The dwarf against the back trellis, he plants eight or ten feet apart. Riders that have been three or four years trained, and are well furnished with fruit-spurs, may be planted between the dwarfs. They may probably yield a few fruit the first season; and will hardly fail to produce plentifully in that following. In the border may be planted, as dwarf-standards, to be kept under five feet in height, some well furnished plants that have been kept in large pots or tubs for a year or two, and such being more fruitful, and less apt to grow to wood than plants that have grown in the open ground. In planting these, the ball of earth should not be very much reduced; only a few of the under roots should be spread out; for if the ball were reduced, and the whole roots spread out, as in the ordinary way of planting, when it is wished that a plant may push freely, the intention here would be thwarted; which is, to have the plant dwarf and fruitful, growing little to wood. Along with these may be planted in the same way, an apricot or two, or figs, or both, that have been dwarfed in pots or tubs, as above. If they succeed, it would give a pleasing variety of the fruit. Some old-growth plants, that have been kept in large pots or tubs for a year or two, and such being more fruitful, are also pulled out, and planted in the back, on account of shading the trees on the trellis. If the planting of the principal dwarfs and riders, let the wood be carefully pruned down, and the young training shoots tied to the ground as possible; placing them just as deep as they have been before; spreading out their roots and fibres, and filling in with fine earth. The whole should have a moderate quantity of water, and have air freely admitted every day; defending them, however, from snow or much rain. The house should not be forced the first year; and it will be better to defer planting in the pots till the middle or end of March, than to prune them now. I shall, therefore, take no further notice of them till then, supposing they are to be attended to with respect to air, and moderate waterings. It is necessary, however, to remark, that the plants should be carefully anointed with the liquor, either just now, or some time in the course of the month.”
3123. Time of planting. According to Nicol and McPhail, January and February; to Torbrum, early in the autumn.

3124. Pruning. "Trees planted in January may be pruned about the middle or end of March. The dwarfs, planted against the trellis, should be well cut in; that is, each shoot of last year should be shortened back to three or four buds, that the plants may throw out a sufficiency of young shoots to fill the rail from the bottom. The dwarfs, planted in the border as little standards, need not be headed in so much; as the intention is to have them fruitful, and that they may grow little to wood from the beginning. Their short stubby shoots need not be touched, unless bruised or hurt in transplanting; shortening back the longer and weaker ones only, a few inches, according to their strengths. The riders, planted against the back trellis, may be treated very much in the same manner; the sole intention being to obtain a few crops of them while the dwarfs are making wood and filling their spaces. In November following, the trees may be pruned for the succeeding season. In order to produce wood to fill the trellis as soon as possible, the dwarfs should be pretty much headed in. The shoots may be pruned very much in the manner of the trees in the early house, shortening no shoots that are fully ripened, except a few of those at the extremities of the tree, in order to make them throw out others for its full extension upwards next year. November is also the proper time for pruning an established cherry-house, preparatory to forcing for next year. As cherry-trees which have been forced make very little wood, very little pruning is required; probably nothing further than moderately to thin out the spurs, and to prune off any accidental breast-wood or water-shoots that may have risen since the crop was gathered. The leading shoots, except for the purpose of producing wood to fill up any blank or vacancy, need not be shortened; nor need those in the lower parts of the tree, except for the same reason. But if it be necessary to shorten these, let them be cut pretty well in, as otherwise they will push very weakly. Shoots on the extreme parts of the tree, that should be shortened for the above purpose, need not, however, be cut so closely in. If they be headed back one third, or to half their lengths, it will generally be found sufficient."

3125. Summer pruning. Very little of this is requisite, such water-shoots or breast-wood as arise among the spurs are to be pinched off as they appear; laying in such shoots only of this description as may be wanted to fill an occasional vacancy. Train in the summer shoots of the dwarfs as they advance, at the distance of about eight or nine inches from each other; and otherwise observe the general rules for pruning cherries on walls and espaliers.

3126. Stirring the soil. After pruning, the borders are to be forked up, and a little well rotted dung, mixed with sand, worked in, if thought necessary. In summer, they may be slightly stirred on the surface, and weeded to keep them fresh, clean, and neat, and where a part of the border is outside the house, cover with horse-dung or litter in the early part of the season.

3127. The time of beginning to force is sometimes December, but more generally January or February. "Newly planted trees," Nicol observes, "will bear gentle forcing next spring, from the first or middle of March; which ought to be considered merely as preparatory to forcing them fully, from about the first of February, the third year." Torbrum, if the trees have been removed with good balls, admits of gentle forcing the first spring, but prefers deferring it till the third year. He says, "I have had an abundant crop of fine cherries, from trees which had been planted only a few months before forcing, but would not recommend the risking a whole crop, unless the trees have been longer established." Where cherries are to be ripened early in the season, he "shuts in about the beginning of December, and lights the fires about the third or last week of that month."

(Hort. Trans. iv. 116.)

3128. Temperature. Abercrombie begins at 40°, "and throughout the first week, lets the minimum be 40°, and the maximum 42°, giving plenty of air. By gradual advances in the second, third, and fourth week, raise the course to 42° min. 45° max. In strong sunshine, admit air freely, rather than have the temperature above 52°, by collecting the warm air. In the fifth and sixth week, the artificial minimum may be gradually elevated to 45°, but the maximum should be restrained to 48° from fire-heat, and to 55° from sun-heat, until the plants are in flower. After the blossoms are shown, and until the fruit is set, aim to have the heat from the flames at 48° min. 52° max. At this stage, maintain as free an interchange of air as the weather will permit; and when the sun is strong, do not let the temperature within exceed 60°. As the fruit is to be swelled and ripened, the requisite heat is 60 min. 65° max."

3129. McPhail, in January, "does not let the cherry-house rise higher than 35°. In February, "If the thermometer in a morning is as low as 35°, there is no danger; but it should rise in the course of the day, to imitate nature as near as possible. In the month of March, the thermometer in the open air in the shade seldom rises above 55°. In the month of April, it seldom rises above 60°. But it is observed, that when the sun shines on a cherry-tree or other trees in the open air, the heat on them is higher than in the shade. The cherry-tree is of such a delicate nature to force, that it is impossible for any person to write down the exact temperature of the air, which would ensure a crop of fruit from it in the forcing way."
CULTURE and first but always not, after this, the thermometer may be regulated by the fire-

heat, which is kept down to 50° or 55°. In March the fruit, will be setting, and the temperature of the house must therefore be kept as steadily as possible to about 50°, lest the fruit drop; this being the most critical period of the forcing with all stone-
fruits. In April the fruit will be beginning to color and swell off for ripening, when the temperature may be raised four or five degrees.

Torbrpn says, “For the first three, four, or five weeks of lighting fires, if the weather be so severe as to depress the thermometer in the open air from twenty-two to twelve degrees; then let the thermostat or the thermometer be kept at forty-five or five by-five; for in this case the frost. If the weather be not severe during the above period, the thermometer may be kept to forty-five inside the house. As the season advances and becomes more mild, and the days longer, probably about the first or middle of February, the thermometer may be raised to fifty degrees, and then it is expec-
ted that the air temperature, two or three degrees above the outside air temperature, the trees are in bloom, no sprinkling must be used; but the flames, when only moderately hot, are to be steamed from before; fruit the most critical period of the forcing with all stone-
fruits. In April the fruit will be beginning to color and swell off for ripening, when the temperature may be raised four or five degrees, the house being engined three or four times a week in the evening; but never till the bloom is all down. When the cherries are completely stoned, the thermometer may be raised to sixty degrees by fire-heat, sprinkling every evening by engine, till the fruit is nearly ripe; the house may be kept higher by day, as well as by night, after stoning. (Hort. Trans. iv. 118.)

Watering. M’Phail waters occasionally at root and over the top, till the trees are in blossom; but when the stones in the fruit are become hard, the trees may be washed all over occasionally with clean water, not too cold. “Let this be done in a fine sunny morning, and take care not to spatter the fruit with any kind of dirt. In April, when the cherries are grown large, give the border a good watering now and then, which will enable the trees to swell their fruit to a good size: by keeping them in a healthy growing state, the fruit will be fine-flavored, and the trees will make strong flower-buds for the ensuing season. If the fruit are not ripening, wash the trees occasionally, in a fine sunny morning, with sweet clean water.”

Nicol, after he begins to force in January, “gives moderate supplies of water at the root; and once in two days, let them be well scoured with the engine; first right and then left. This is done to re-

fresh the branches and infant foliage; but chiefly, at this time, for the suppression and prevention of in-
sects that are as troublesome here as in any other forcing-house, and are easier kept down than brought down. For, of all the cereals, the plants must have regular and moderate supplies of water at the root till the fruit be set, and then no water must be admitted as their foliage and young branches will be exercised upon their branches, in a moderate manner, once in two days; generally in the afternoon, about three or four; always use well air'd soft water. But from the time the flowers begin to open, until the petals begin to drop again, desire of using the engine, difficulty. At this interval, the foliage must be refreshed by

steam, which may be produced plentifully every evening, by pouring water on the flames when the fire is at the strongest. A very fine dew might be thrown on the plants by a soft syringe; but as soon as the fruit is set, the engine is the instrument we should trust to for the suppression of insects.” In March, the fruit will be setting, and till this is completed, “the border should be kept rather in a drier state than usual; lest if it be kept too moist, it may occasion their dropping; but afterwards, let it be regularly and freely watered, in order to promote the growth of the plants, and the swelling of the fruit. Now arrange the watering, so as to open up moist and free a day; and in the day, the sup-

pression of the red spider, and to keep the plants clean.” In April, “when the fruit begins to color and swell off, withhold water from the border by degrees, and towards their being ripe, entirely. At this time, also, watering with the engine must be withheld; but previously exercise it with force, and often, for a week or so; as long as danger is apprehended, if he be able to anoint the fruit with the atmosphere. After this, if the weather is gathered, these waterings must be resumed, and should be continued till the foliage begin to drop; not, however, so much on account of the cherry-trees, as on account of other plants that may be placed in the house; for if the enemy be allowed a footing on the former, he will soon show himself on the latter, where perhaps he will be more vulnerable. In March, if the border be of a tender kind. The border may be kept in a moderately moist state till the leaves fall, or till the house be exposed, or be uncovered.”

Torbrpn says, “From the time the flower begins to open, till the fruit is completely stoned, the soil should be sparingly watered; but when the stoning is effected, water may be applied to the root freely, till the fruit is nicely ripe.” (Hort. Trans. iv. 118.)

Air. “In forcing the cherry, it is essential to continue a free renovation of air; always sustaining the minimum heat in the different stages. The blossoms will sometimes fall abrasive, or the young fruit drop off after setting, from no other cause than a stagnant atmosphere.” At first beginning to force, M’Phail gives plenty of air night and day. In February, when the trees are in blossom, “let air be at the house day and night; and as much as you can when the fruit are swelling off.”

Nicol says, the airing of the cherry-house may be performed by the sashes, with every safety, till the buds begin to expand; and after that, in frosty or bad weather, air may be admitted by the ventilators. In February, nothing is more conducive to the health of the plants, and the setting of the fruit, than a regular and abundant ventilation of air; and if this be denied them for many days together, they will altogether cease to grow. The foliages will become shrivelled, and the flowers wither. A day and a night's air is not less than what is necessary for the fruit; as the fruit ripen, give as large and regular portions of air as possible; opening the sashes by eight or nine in the morning; giving full air about ten; reducing about two-thirds, as long as danger is apprehended, and raising to the full in the evening. In conducting this matter, however, regard must be had to the temperature; but air may be admitted, in sunshine, to such an extent as to keep down the mercury or spirits in the thermometer to 65°, and at other times to 70°. (Kal. p. 36.)

Torbrpn says, “The cherry, in forcing, requiring more fresh air than most other fruits, particular attention must be paid to its admission, by the gardener having it in his power occasionally to make as many inlets or openings as convenient. It is to be conducive to this end, that the roof, and the upright or front sashes, if any, be made wide, and all with little difficulty; because in changeable weather, the current of air may be required to be augmented or reduced many times in one day. Air must be admitted freely and
copiously when the weather is mild and calm, and accompanied with sunshine, during the time the cherries are in bloom, and also near the time of their ripening." (Hort. Trans. iv. 118.)

3139. *Insects, diseases, and depredators.* "The cherry is liable to be infested by a small grub-worm, which rolls itself up in the leaves, and extends its ravages to the fruit. As soon as this insect is perceived, the trees should be searched daily, that it may be destroyed by the hand, and prevented from spreading. It usually shows itself first about the time of flowering. Cherries set, or in blossom, require great attention. Like rose-buds, they are liable to be destroyed by a small grub-worm, which rolls the leaves round itself, occasionally, for a covering: it preys on the leaves as well as the fruit. The trees should be searched once or twice a-day, to destroy them with the hand as soon as they can be observed. Whenever a leaf appears to begin to curl, be sure there is an insect in it, or the embryo of one. The cherry-house, as the season advances, may be smoked once a-week or ten days, which will prevent the trees from being infested with a blackish kind of insect, frequently very pernicious." (Gard. Remem. 161. 191.) When the fruit are ripe, it is likely the birds will fly in and eat them, if you do not contrive nets, or some other method, to keep them out. If the meshes of the nets which you employ are narrow, the wasps and flies, as well as the birds, will be prevented from getting in; for, as these insects generally fly in, they therefore require room for their wings extended, otherwise they are repulsed in their attempt. (Gard. Remem. p. 246.)

3139. Nicol, after every winter pruning, washes the trees over with the mixture of soap, sulphur, &c. already mentioned (3061.); and in spring and summer waters over the leaves, picks off grubs, and fumigates, like M'Phail.

3140. *Torbron* fumigates for the black fly, and picks off the grub.

3141. *Gathering and keeping the fruit.* If it be found necessary, cherries will keep for some time on the trees, provided the birds can be kept from them. Keep the house, for this purpose, dry, cool, and well aired. (Gard. Remem. 246.)

3142. *Exposing the wood.* This, according to all the authors quoted, may be done from the time the fruit is gathered, till within a week or ten days of the recommencement of forcing. The glass should be entirely taken off, unless the cherry-house is in part used for some other purpose, to which this practice would be injurious.

3143. *Forcing cherry-trees in pots.* M'Phail and Nicol concur in approving the very general practice of planting cherry-trees in pots; in which, or in tubs of a foot or fifteen inches diameter, they may be successfully forced. "Three or four dozen good plants, well managed in this way, would give a deal of fruit; which might be had in succession for a considerable length of time, by dividing the plants into three or four classes or divisions, and shifting them from one compartment to another. In January, the first twelve trees may be placed (from the open air, of course,) in the green-house or conservatory, if there be one, or in a peach-house now at work; placing them in the coolest part of the house, but in the full light, and where they may have plenty of air. They must be duly attended to with water at the root, and be frequently syringed at top, generally once in two days. The pots being occasionally watered with the drainings of the dunghill, would add much to the vigor of the plants; there is no method of manuring more effectual, or so easily accomplished. The plants may remain here till the fruit be fairly set, the stoning over, and all danger of dropping be passed. They may then be placed in a vineyard or stave to ripen off, where they would come in early, and be very high-flavored, if placed near the light, and so as that they might have free air daily. In February, a second and third dozen should be taken in, and a fourth in the beginning of March, and each similarly heated." (Kalend.) "It is very common with early forced cherry-trees to bear a second crop late in the same season." (Hort. Trans. iii. 367.)

3144. *Forcing by a temporary structure.* Torbron observes, that, "where a portion of wall (especially with a southern aspect), already well furnished with May-dukes, perfectly established, and in a bearing state, can be spared for forcing, a temporary glass case may be put up against it; the flue may be built on the surface of the border, without digging, or sinking for a foundation; neither will any upright glass or front wall be requisite; the wooden plate on which the lower end of the rafters are to rest may be supported by piles, sunk or driven into the soil of the border, one pile under every, or every alternate rafter. The space between the plate and the surface of the soil should be filled by boards nailed against the piles, to exclude the external air, for the plate must be elevated above the level of the surface from eighteen to thirty inches, or whatever height may be sufficient to let the sashes slip down, in order to admit fresh air. I believe this to be an uncommon structure, and it may perhaps be objected to: but I am confident that it will suit well for cherries, for I have constructed such places even for forcing peaches with good success, as well as for maturing and preserving a late crop of grapes." (Hort. Trans. iv. 117.)

**Sect. V. Of the Culture of the Fig-house.**

3145. *A house for forcing the fig* is seldom built expressly for that purpose; partly from there being no great demand for the fruit in most families, and partly because figs
are generally forced in pots or tubs placed in the peach or cherry-house, and managed as these trees. The fig-tree, when forced, is very apt to cast its fruit before it is half swelled. "A separate hot-house," Neil observes, "is but seldom erected for the cultivation or the forcing of the fig; a few dwarf-trees, such as the brown Italian, and purple Italian, introduced into the peach or cherry house, being by most people thought sufficient. It has been found by experience, that dwarf-standard fig-trees, planted in the middle of a vinery, between the flues, and thus under the shade of the vines, bear fruit plentifully, ripening both the spring and autumn crops. This may be seen in the vinery erected by Hay, at Preston Hall, near Edinburgh." (Ed. Eu. art. Hort.) Sabine recommends training fig-trees on the back walls of vineries, where he has seen them answer well, the vines being trained immediately under the roof. He says, "It is advisable not to train the vines entirely under the whole of the glass, but to leave a space in the centre of each light, its whole length, for the admission of the sun's rays;" judiciously adding, "the grapes will be perhaps as much benefited by this practice as the figs." (Hort. Trans. iii. 410.)

3146. The soil for fig borders, or plants in pots, is in all respects the same as that for the cherry.

3147. Choice of sorts. Abercrombie recommends the

| White Genoa | Chestnut | Black Ischia | Brown Ischia | Black Genoa | Malta |

3148. To which Nicol adds the brown Italian, and black and purple Italian.

3149. Choice of plants. Such as are two or three years trained, either as wall or dwarf standards, are to be preferred.

3150. The situation of the plants in the house is generally against a back wall trellis.

3151. Pruning. Figs are to have a spring and summer pruning; both of which, Nicol observes, may be comprised in one, by rubbing or pinching off the infant shoots, thought necessary to be displaced, in order to give the tree air, and strengthen such as remain. The summer pruning, or rather thinning, consists chiefly in keeping them moderately thin of leaves, so as not to overshadow the fruit. Sabine's trees are pruned in the autumn, after their wood is well hardened; but as "the object is to get the trees to the largest possible size, in which state they will produce more of the short fruit-bearing shoots, they are cut but little, except it be occasionally necessary to thin them, by taking out a strong limb." (Hort. Trans. iii. 410.) Fig-trees, intended to bear fruit abundantly, should never be allowed to produce suckers, or any shoots from the main stem, within eighteen inches of the ground; fan-training is in general the best method, and the points of the young shoots may be turned downwards, where it can be done without producing fracture, or inducing them to throw out shoots by the strain requisite for this purpose.

3152. Stirring the soil, &c. After the gathering of the fruit, the borders are to be forked up and manured, if necessary, as in the cherry-house, and in summer weeded and refreshed.

3153. The time of beginning to force is generally the same as that for the cherry or peach house: December, January, or February. Sabine, in the case above referred to, where the trees are planted against the back wall, says, "the time of beginning to force is in the middle of April; the first crop of figs ripens in June, and the second crop in August." (Hort. Trans. iii. 410.)

3154. Temperature. "From the leafing time," Abercrombie observes, "till the ripening of the fruit, the fig requires a temperature between that scale which is proper for the peach, and that for the cherry." McPhail says, "They require a greater degree of heat than the cherry." When bringing forward their fruit, they will bear a good strong heat, if care be taken to keep a free circulation of air moving out of and into the house. (G. Rem. 147.)

3155. Water. Fig-trees in a house, and especially those in pots, require abundance of water in the stages suitable for watering fruit-trees. (Abercrombie.) McPhail says, "The border in which fig-trees grow, should be kept sufficiently watered, till May, when watering over the leaves may be commenced."

3156. Air. When the figs are planted under glass, Miller observes, "The heat should not be too great, nor the glasses or other covering kept too close, but at all times, when the weather is favorable, a good share of free air should be admitted. In this respect the fig does not greatly differ from the vine, though it will thrive with less air than any other fruit-tree." (Dict. in loco.) In summer, as the fruit advances, water even in that part of the border which is without the house. Refrain from watering over the leaves and fruit, when the latter begin to ripen. (G. Rem. 192.)

3157. Insects. Very much pains, Nicol observes, should be taken to suppress the red spider on the foliage of figs; whether by the engine, syringe, or by frequently brushing with a painter's sash-tool, the under sides of the leaves, "in order to destroy his webs, which are there thickly woven." Few other insects annoy the fig, except sometimes the coccus
or scaly insect; which is destroyed by washing with soap-suds and sulphur: or the liquor recommended for destroying that insect on pines. (Kal. 319.)

3158. Gathering the fruit. Figs begun to be forced in January, Nicol states, will be ripe about the end of June and July. "If fig-trees in a forcing-house," Miller observes, "are properly managed, the first crop of fruit will be greater than upon those which are exposed to the open air, and will ripen six weeks or two months earlier, and a plentiful second crop may also be obtained, which will ripen early in September." To preserve the bloom, gather with the peach-gatherer. They may be preserved a short time on the trees, by covering with mats from the sun, and admitting abundance of air among the branches. This alludes to what is called the second crop, or that produced from the wood of the current year. Sometimes a few of the first crop ripen, but in general it is not to be relied on. Aiton, Sir Joseph Banks informs us (Hort. Trans. i. 253.), "has for several years practised the forcing of figs in the royal gardens of Kew, with great success, and his chief dependence is on the second crop."

3159. Exposure of the wood. After the fruit is gathered, the glasses may be removed, till winter sets in, when they must either be put on, or the trees covered with mats or straw, to protect them from the frost.

3160. Forcing the fig in pots. M'Phail says, figs may be ripened at an early season, by planting them in pots, and setting them into a hot-house or forcing-house. "The plants should be low and bushy, so that they may stand on the curb of the tan-bed, or they may be plunged in a gentle tan-heat, or in a bed of leaves of trees. The best way to propagate plants for this purpose is to take layers or slips which have good roots: plant them in pots in good earth, one plant in each pot, and plunge them in a bed of tan or of leaves of trees, in which is a very gentle heat: a brick bed will answer the purpose very well; or they will do in the forcing-house, if there be room for them. Let them be put into the house in the latter end of February or beginning of March, and keep them sufficiently watered. When they are two years old, they will be able to bear fruit; the pots in that time having become full of roots. In the month of November or December, turn the plants out of the pots, and with a sharp knife pare off the outside of the ball, by which the plant will be divested of its roots matted against the inside of the pot: then place them into larger pots, filling up the vacancy round the balls with strong loamy earth. During the winter, let them be kept in the green-house, or in a glazed pit of a like temperature, till the month of February; then set them into the forcing-house, where it is intended they shall ripen their fruit. In this manner let them be treated every year, which will be a means of preventing the fruit from falling off before it come to maturity." (G. Rem.) Nicol says, fig-trees kept in pots or tubs, may be treated very much as directed for cherries. Two dozen, or thirty plants, would be a good stock for that purpose. The first division might be placed in a cherry or peach-house about the middle or latter end of January. (Kalender, 319.)

3161. Culture of the fig-tree in the stove. The fig formed one of the different species of trees which Knight subjected to a very high temperature during bright weather, and a comparatively low temperature during the night. (Hort. Trans. iii. 459. 1212.)

3162. The large white fig-tree succeeded perfectly, "just ripening its spring figs, (those which usually ripen in the open air in this country,) and afterwards its summer figs. The trees then produced new leaves and branches; and the fruit, which would have appeared in the next spring, ripened in high perfection in September. Subsequently also, a few of those, which, in the ordinary course of the growth of the tree, would have appeared as the summer crop of next year, have ripened, and these, though inferior to those of the preceding crops, have not been without merit. At the time this communication was made, this fourth crop was only beginning to ripen, and was thought of inferior quality; but Knight informs us, in a subsequent communication (read July 18, 1820), that "the subsequent portion of it proved most excellent; and some figs which were gathered upon Christmas-day, were thought by myself, and a friend who was with me, much the best we had ever tasted. The same plants have since ripened four more crops, being eight within twelve months; and upon a ringed branch of the one year old, and about an inch in diameter, a ninth crop, consisting of sixty figs, will ripen within the next month. I possess only two plants, each growing in a pot, which contains something less than fourteen square inches of mould, and occupying together a space equal to about sixty-four square feet of the back wall of my pine-stove; from which a number of figs have been gathered within twelve months has been little, if any, less than 300; and I see every prospect of a succession of crops till winter. I therefore send the following account of the mode of culture, which has been employed, in the hope that it may prove useful to those who wish to follow me: let it be done in a place which has a sufficient temperature. My trees grew, as I have seen, in the communication to which I have above alluded, in exceedingly rich mould, and are most abundantly supplied with water, which holds much manure in solution. They consequently shoot with great vigor, notwithstanding the small space to which their roots are confined; and they require no care to restrain them in their growth. In the limits assigned to them; but I have found the following mode of treatment perfectly efficient and successful. Whenever a branch appears to be extending with too much luxuriance, its point, at the tenth or twelfth leaf, is pressed between the finger and thumb, when the roots come in contact, and the bark of the twigs is diseased: a succulent substance is felt to yield to the pressure. Such branch, in consequence, ceases subsequently to increase, and the sun's heat is entirely expended where it is more wanted. A fruit ripens at the base of each leaf, and during the period in which the fruit is ripening, one or more of the lateral buds shoots, and is subsequently subjected to the same process. When I have observed paper to have been taken off in a length of 10 feet, I have found that a small part of them only became productive, either in the same, or the ensuing season, though I have seen that their buds obviously contained blossoms. I made several experiments to obtain fruit in the following spring from other parts of such branches, which were not successful; but I ultimately found that bending these branches, as far as could be done without danger of breaking them, rendered them extremely fruitful; and in the present spring, thirteen figs ripened upon a
branch of this kind, within the space of ten inches. In training, the ends of all the shoots have been made, as far as practicable, to point downwards." (Hort. Trans. iv. 202.)

3163. For various opinions and practices in pruning and training the fig in the open air, which may also deserve attention in the forcing department, see the Horticultural Catalogue.

Sect. VI. Of the Culture and Forcing of the Cucumber.

3164. To produce cucumbers at an early season, is an object of emulation with every gardener; and there is scarcely any person, not even the humblest tradesman, as McPhail observes, who has not his cucumber-bed in his garden. We shall follow our usual plan, and lay before the reader a systematic view of the practices of the most approved gardeners in the culture of this plant. Cucumbers are forced in hot-beds, pits, and hot-houses; and the heat of fire, and steam, and dung, have been applied to their culture; but dung, as the author last quoted observes, is the only thing yet found out, by the heat of which the cucumber may be advantageously cultivated.

3165. Soil. Cucumbers, like every other plant, will grow in any soil, though not with the same degree of vigor, provided they be supplied with a sufficiency of heat, light, water, and air.

3166. Abercrombie, for early forcing, recommends a mould or compost of the following materials:—

"One third of rich top-slip earth, from an upland pasture, one half of vegetable mould, and one sixth of well decomposed horse-dung, with a small quantity of sand." Abercrombie used vegetable mould, made from a mixture (accidental) of the leaves of "elm, lime, beech, sycamore, horse and sweet chestnut, spruce and Scotch fir, walnut, laurel, oak, evergreen oak, ash, &c." and among them withered grass, and weeds of various sorts. "This vegetable mould," he says, "without a mixture of any thing besides, is what I used for growing cucumbers in, and, by experience, I found it preferable to any other moulds, earths, or composts whatever, either in my new method of a brick bed, or in the old method of a bed made of hot dung."

3167. Nicol says, soil thus composed will produce cucumbers in great abundance: "Three fourths light, rich, limy earth, from a pasture, an eighth part vegetable mould of decayed tree leaves, and an eighth part rotten cow-dung." (Kat. p. 393.)

3168. Aiton gives the following as the compost used in the Kew-garden: "Of light loam, a few months from the common, one third part; the best rotten dung, one third part; leaf-mould and heath-earth, of equal parts, making together one third part; the whole well mixed for use." (Hort. Trans. vol. ii. p. 282.)

3169. Mills (Hort. Trans. vol. iii. p. 148.) states, that the soil he uses "is half bog or black mould, got from a dry healthy common, and half leaf-mould; after lying twelve months in a heap, the compost is fit for use."

3171. Time of beginning to force. Abercrombie says, "Managers who have to provide against demands for early cucumbers, must raise the seedlings from twelve to ten weeks before the fruit will be required, according to the length of the days in the interval. In proportion as the entire course embraces a greater part of midwinter, the liability of failure from obstacles in the weather will be greater. The last fortnight in January, or first week of February, is a good time for beginning to force the most early crop. In the subsequent months, both main and secondary crops may be started as required; and will come forward more freely. To have a constant succession, seedlings should be originated twice a-month. As the course of forcing more coincides with the natural growing season, the length of it will be reduced to eight, seven, or six weeks."

3172. McPhail says, "Those who are desirous of having cucumbers early, had best sow the seeds about the 20th of October; they may be sown at any time of the year, but the spring and autumn are the best seasons. Cucumber-plants may be made to bear fruit plentifully from about the middle of March till the middle of September; but from the middle of September till the middle of March their produce will be but scanty. Cucumber-plants raised from seed in October, will begin to produce fruit in February or March, and will continue to bear till the following month of October, provided they be kept in frames, and get plenty of heat and water." Nicoll recommends the middle of January. He says, "Some begin sooner, but it is striving hard against the stream to little purpose. If the dung be prepared, and the bed be got ready, so as to sow about the 1st of February, the success will often be greater than by sowing a month earlier; the growth of the plants being frequently checked by bad weather, and sometimes they are entirely lost."

3174. Aiton, in the paper above quoted, sowed on the 12th and 30th of August, with a view to cultivate in stoves; a regular supply of this vegetable being annually required for the royal tables.

3175. Mills sows on the 16th of October.

3176. Sorts. Abercrombie recommends "the short prickly for very early fruit; and the long prickly kinds for the chief early and main summer crops." McPhail prefers "the green cucumber with black prickles, as best for forcing. When fit for table, it runs from six to nine inches long, and, when ripe, runs to about eighteen or twenty inches long." Nicol says, "Every gardener has his favorite sort of cucumber, and it is no easy matter to advise. He names, as early sorts generally known, the early short prickly as the earliest; the early smooth green, a long fruit; the long green prickly, and the white prickly, a white fruit." Aiton and Mills do not mention the varieties they used.

3177. Choice of seed. "It is advisable," Abercrombie observes, "to have that from two at least to four years old, in preference to newer seed, which is more apt to run luxuriantly in vine, and the plants from it do not show fruit so soon, nor so abundantly as those from seed of a greater age. But when seed has been kept more than four years, it is sometimes found to be too much weakened."
3178. *Forming the seed-bed.* "A one-light frame," Abercrombie says, "will be large enough for ordinary purposes. Choose a dry sheltered part of the melon-ground, and form a bed for a one-light frame. When high winds are suffered to blow against a cucumber-bed, they have a very powerful effect on it; for, in that case, the heat in a short time will not only be greatly abated, but also forced and driven into the corners of the frames, and, consequently, some parts thereof are rendered too cold, whilst other parts are made too warm; and, of course, the plants are all equally endangered, retarded in their growth, and perhaps some, if not all of them, totally destroyed. Therefore, when a cucumber-bed is about to be built, the first object of consideration should be, to have it, as well as possible, sheltered from the high winds and boisterous stormy weather. Having put on the frame, and waited till the bed is fit for moulding, lay in five or six inches depth of the proper earth or compost." 3179. *M'Phail makes up a bed of good dung, four feet high, or a one-light box.* 3180. Nicol builds a bed of dung, carefully fermented, to the height of five feet at back, and four at front, keeping it a foot larger all round than a one-light frame, or about five or six feet by three or three and a half. He then covers with turf; and on that lays fine sand, as free from earth as possible, to the depth of about six inches; laying it in a sloping manner, corresponding with the glass, and to within six inches of it; over which he lays an inch or two of dry light earth. 3181. *Aiton and Mills also prepare a bed for a one-light box,* the latter forms it on a stratum of wood one foot high for drainage, and eight inches higher in the middle than at the sides, as the sides are liable, from the weight of the frame, to settle faster than the middle, which causes the hills of earth to crack; by which, in fruiting-beds more especially, the roots of the plants are greatly injured. 3182. *Sowing.* Abercrombie sows some seeds in the layer of the earth, which he spreads over the bed, putting them in half an inch deep. He also sows some seeds in two, three, or more small pots of the same kind of earth, which may be plunged a little into that of the bed. 3183. *M'Phail sows in a pot filled with rich earth, covers about two inches thick, and sets the pots on the surface of the naked dung on the bed.* 3184. Nicol sows immediately after the bed is made, without waiting till the heat arise, which, he says, is losing time, and the opportunity of bringing on vegetation by degrees as the heat rises. He sows in a broad pan four inches deep, or in small pots four or five inches diameter, and as much in depth. These he fills with a fine light earth, or vegetable mould, and covers the seeds two inches. He ploughs these to the brim in the back part of the bed (which it will be recollected contains a stratum of earth six inches thick over one of sand, and another of turf), puts on the light, and lets the frame be matted at night in the ordinary way. 3185. *Raising plants from cuttings.* M'Phail says, "Instead of raising cucumber-plants from seed, they may be raised from cuttings, and thus kept on from year to year in the following manner: "The method of striking them is this; take a shoot which is just ready for stopping, cut it off just below the joint behind the joint before which the shoot should have been stopped, then cut smooth the lower end of the shoot or cutting, and stick it into fine leaf or other rich mould about an inch deep, and give it plenty of heat, and shade it from the rays of the sun till it be fairly struck. By this method, as well as by that of laying, cucumber-plants may readily be propagated." 3186. *Mears, gardener at Shobden Court, near Leominster, propagates his cucumber-plants for a winter crop in this way, and finds, that the plants raised from cuttings are less succulent, and therefore do not so readily damp off, or suffer from the low temperature to which they are liable to be exposed in severe weather; that they come into bearing immediately as they have formed roots of sufficient strength to support them, and do not run so much to barren vine as seedlings are apt to do." He takes the cuttings from the tops of the bearing shoots, and plants them in pots nine inches deep; half filled with mould. He then waters them, covers the tops of the pots with flat pieces of glass, and plunges them into a gentle bottom heat. "The sides of the pot act as a sufficient shade for the cuttings during the time they are striking, and the flat glass, in this and in similar operations, answers all the purposes of bell-glasses. The cuttings form roots, and are ready to pot off in less than a fortnight." (Hort. Trans. iv. 411.) 3187. *Temperature of the seed-bed.* Abercrombie says, "The minimum heat for the cucumber is 58 degrees at the coldest time of night; in the day-time 65 degrees is sufficient for the maximum; because air admitted when the sun has great influence, will do more good than a higher heat." 3188. *M'Phail says,* "If it were possible to keep the heat in the frames always to 80 degrees, with the concurrence of proper air and moisture, I am of opinion that that would be a sufficient heat for the production of the cucumber." 3189. *Nicol keeps the air in the bed to about 65 degrees in the night, allowing a few degrees of a rise in sunshine.* 3190. *Aiton rears and fruits his plants in a stove,* and therefore we shall take no farther notice of his practice at present. 3191. *Mills says,* "The heat I wish to have in the seed-frame is from 65 to 75 degrees." 3192. *Treatment till removed to the fruiting-bed.* "After sowing, Abercrombie continues the glasses on the frame; giving occasional vent above for the steam to evaporate, that the bed may keep a moderate heat, and not become too violent. The plants will be up in a few days, when it will be proper to admit air daily, but more guardedly, at the upper ends of the lights, which may be raised from half an inch to an inch or two, according to the temperature of the weather, that the plants may not draw up weak, or be injured by the steam. In frosty weather, hang part of the mat over the aperture. When the plants are a little advanced, with the seed-leaves about half an inch broad, take them up, and prick some in small pots of light earth, previously warmed by the
heat of the bed. Put three plants in each pot, and insert them a little slopingly, quite to the seed-leaves. Plunge the pots into the earth; and you may prick some plants also into the earth of the bed. Give a very little water just to the roots: the water should be previously warmed to the temperature of the bed. Draw on the glasses; but admit air daily, to promote the growth of the plants, as well as to give vent to the steam rising in the bed, by tilting the lights behind, from half an inch to an inch or two high, in proportion to the heat of the bed and temperature of the weather. Cover the glasses every night with garden-mats, and remove them timely in the morning. Give twice a week, once in two or three days, according to the season, a very light watering. Keep up a moderate lively heat in the bed, by requisite linings of hot dung to the sides.

3193. M'Phail, having sown and placed the pots on the naked bed, says, the plants will come up in a few days; and when they have fully expanded their two seed-leaves, transplant them into small pots, three plants in each pot; set them on the surface of the dung in the bed, and let a little air be left at the light day and night, to let the steam pass off freely. If the seedling plants have one or two joints, stop them by breaking them off with a pair of shears; if three, cut them in two at the third joint, and then stop them; and afterwards continue throughout the season to stop the plants at every joint.

3194. Nicol directs to guard the seedlings from mice, which generally swarm about hot-beds, by laying a pot cover over the pot or pan till they show about an inch; and afterwards, at night, by covering with a pot of equal size, till the seed-leaves have expanded, and the huds have dropped; for, until then, the plants are liable to be destroyed. The cover, however, should always be removed by sunrise, and replaced in the evening. It is at night these vermin generally commit their depredations. No air need be admitted till the heat begin to rise, and steam begin to appear; but after that, the light should be tilted a little every day, in whatever state the weather may be, until the plants break ground. Air must then be admitted with more care; and, if frosty or very chilly, the end of a mat should be hung up over the opening, the sides being closely drawn up, and then admitting a little air. A little air, or a very little aird water may be given once a day, from the time the seeds begin to chip; and if a very strong heat rises, the pots should be raised a little, to prevent the roots from being injured. They should be frequently examined on this account, and if the heat be violent, should be set loosely in the sand, or be placed entirely on the surface. The air of the bed may be regulated in height; allowed to be slightly increased, or decreased, according as the weather be severe, therefore, the mats must be doubled or tripled; and if mild, perhaps a single one may suffice. But, unless in very bad weather, they should always be removed by sunrise, in order to admit the natural air to the plants, which, in such circumstances, is of the greatest utility. Put a little aired water, in order to settle the earth to the roots of the plants.

3195. Pricking out. When the plants are about an inch and a half high, they are then fit to be pricked out into nursing-pots. These pots should be about three and a half or four inches diameter at top, and as much in depth. The mould to be used should be the same as that the seeds were sown in, and should be laid in the pots as a few hours previous to pricking out. In order to bring it to a proper degree of warmth, that the tender floris may not be chilled by it. Let the pots be filled about one half full with the earth; turn the plants carefully out of the seed-pot; place three in each against the side of the pot, and so as that their leaves may be just above its margin; then cover the roots with the mould, rubbing it fine between the fingers; and pressing it home. Work over the stems, and on the top of the leaves, to make their sides concave; or plunge the pots to within an inch of their rims; and cover the whole surface with a little dry earth as at first, making it level with the tops of the pots. Then give a little aired water, in order to settle the earth to the roots of the plants.

3196. Second sowing. As these tender seedlings, at this early period, are liable to many accidents, it will be proper to sow a little more seeds of the same kind at this time, in order to provide a supply of plants. If they should not be wanted, the trouble is not much; and they may be given to a neighbor, or be thrown away.

3197. Routine culture. Let air be admitted to them as freely as the state of the weather will allow; and supply them moderately with water once in two or three days. Examine the pots frequently, if the heat be violent, lest the roots be scorched; setting them loosely, or pulling them up a little in that case; or, if the heat be, as is frequently the case, arising from the earth in the bed at this time, it may be proper to leave the light tilted half an inch in the night; observing to hang the lip of a single mat two or three inches over the tilt. But if the bed was carefully turfed over, as directed at making up, this will seldom be necessary; never but in thick hazy weather. Mat up carefully at night; but make a pot of earth, or else raise the plants a little, uncover them, and let them be daily exposed. Frequently wash or wipe the glasses clean, outside and inside, as they are often clogged by a mixture of steam and dust. Also, occasionally stir the surface of the sand or earth in the frame with the point of a stick, in order to extinguish vapor that hovers on the surface, and so purify the internal air of the bed. If the heat begin to decrease, and particularly if the weather be severe, it may be necessary to line one or more sides of the bed, that the plants may receive no check in their growth. If it be a one-light box, both back and front may be lined at the same time; and, if necessary, in ten or twelve days, the two sides; and if much steam arise from the linings after they come into heat, be careful, in matting at night, to tuck up the edges of the mat, lest it be thrown into the bed.

3198. Mills, as soon as the seed-leaves of the plants are fully expanded, transplant them singly into pots of four inches. This gives a little water and air and night. Day, and makes the plants for seed easy; but for seed-leaves, as the earth in the pots becomes dry, and a little air and night and day, so as to keep the internal air in the frame sweet, and fluctuating between the degrees of heat above mentioned, the plants will be fit for finally transplanting out in one month, that is, by the 14th of November, into the fruiting-frames. (Hort. Trans. vol. iii.)

3199. Forming the fruiting-bed. Abercrombie directs, When the plants are advanced in some tolerable stocky growth, that is, when the first rough leaves are two or three inches broad, or when the plants have been raised about five weeks, transplant them to a larger hot-bed, with a two-light or three-light frame, sometimes called the ridging-out bed. Form the bed on general principles, of superficial extent according to the frame it is to support, leaving from four to six inches all round, and fixing the height according to the season. Thus, in January, Abercrombie directs the bed to be "three feet nine inches high in front; four feet six inches at the back; and six inches larger than the frame all round: in February, three feet three inches high at the front; four feet at the back; and four inches to spare round the frame: in March, three feet high in front; three feet six inches at back; and four inches beyond the frame every way. Put on the frame and glasses presently after the body of dung is built up, to defend it from the weather. At the same time raise the glasses a little at the upper
end, in order both to draw up the heat sooner, and to give vent to the rising steam, until the bed is reduced to a regular temperature. In connection with the thermometer, the cultivator may be assisted to form a judgment of this, by **trying-sticks**, that is, two or more sharp-pointed smooth sticks, thrust down in different parts of the bed; which at intervals may be drawn up, and felt by a quick grasp of the hand. The smell of the vapor is also a criterion: it should not be strong and fetid, but mild and sweet. While taking care that the heat is not so intense as to burn the mould when applied as below, let it not be suffered to evaporate unnecessarily by delay. If the temperature appear not sufficiently high, take off the frame, and add another course of dung.

3200. *M'Phail*, when he fruits the cucumber on dung-beds, begins to make preparations for the fruiting-bed, about three weeks before the plants are ready to be planted out for good. The dung collected, after being well worked, is *made up* into a bed of about four or five feet high, and the frames and light of glass confirmed. The bed is afterwards covered with straw, which is somewhat abated; and when it is thought to be in a fit state for the plants to grow in, its surface is made level, and a hill of mould laid in just under the middle of each light, and when the mould gets warm, the plants are ridged out in it. After this, if the bed has become perfectly sweet, and there be heat enough in it, and the weather prove fine, the plants will grow freely.

3201. *Nicol* builds his fruiting-bed about four feet and a half high at back, and three feet and a half in front, keeping it fully a foot longer than the frame all round. He turfs it, and lays on sand as in forming the seed-bed, if the dung has not been well fermented. "But otherwise, placing a thick round turf, a yard over, in the middle of each light, so as that its centre may be exactly under the plants, will generally be found sufficiently safe." The frames are now put on; and the beds matted up at night to make the heat rise the sooner.

3202. *Mills* says, "Well preparing the dung, is of the greatest importance in foreing the cucumber, and if not done before it is made into a bed, it cannot be done after, as it requires turning and watering to cause it to ferment freely and sweetly; fresh dung from the stable will require at least six weeks' preparation before it will be fit to receive the plants. A month before it is made into a bed, it should be laid into the bed nine times, threes times, and the water well shaken on. It should then be turned into the middle, and the middle to the outsides, that the whole may have a regular fermentation; and if any appear dry, it should be made wet, keeping it always between the two extremes of wet and dry. A dry spot of ground should be chosen to prepare the dung on, that the water may drain away from the bottom of the heap. The dung having been a month in heap, I make the bed four feet high, form a stratum one foot high, of wood of any kind, but if large the better (old roots of trees, or any other of little value will do); this is to drain the water from the bottom of the bed; for, after a month's preparation, with every care, it will frequently happen, that if left in the air in large quantities, which, if not allowed to pass off freely, will cause an unwholesome steam to rise, in which the cucumber-plant will not grow freely; on this bottom of wood I make the bed, four feet high, with dung, gently beating it down with a fork: this is done about the 1st of November, and by the month of February the four feet of dung will be reduced to two feet, and the two feet reduced to a bed, with the Third the third bed. This I consider a good height, for, if lower, it cannot be so well heated by linings, which is the only method of warming it in the months of February and March, as by that time the first heat of the bed will have quite declined. Having made the bed, I put on the frames and lights, which I shut close together, and allow the rising heat, and day, and night, to allow the steam to pass off, and once in two days I fork the surface over, about nine inches deep, to sweeten it, and if, in the operation, I find any part dry, I carefully wet it. The bed being quite sweet, I prepare it for the mould, by making the middle about eight inches lower than the sides, as the sides are liable, from the weight of the frames, to settle faster than the middle, which often causes the hills of earth to crack, by which the roots of the plants are greatly injured." *Hort. Trans. vol. iii. p. 147.*

3203. **Moulding.** "As soon," Abercrombie observes, "as you deem the bed to have a lively, safe, well tempered heat, which may be in a week or ten days after building, proceed to mould it. Earth the middle of each light, laying the mould so as to form a little hill, from six to ten inches in height, according as seed is to be sown, or plants from the seed-bed inserted. Then earth over the intervals between the hills and the sides of the frame only, from two to four inches, as a temporary measure, until the heat is ascertained to be within safe limit. After the whole bed has been some time covered, examine the mould: if no traces of a burning effect appear, discoverable by the mould turning of a whitish color and caking, it will be fit to receive the plants. But if the earth appears burnt, such part should be replaced by fresh, and vacancies made to give vent to the steam, by drawing away part of the hills from the centre. When the bed is in fit order, level the mould to six inches deep, to receive seeds; but to receive plants in pots, the hills of earth should be kept ten inches deep or more. If there be any motive for haste while an excess of heat is to be suspected, the danger from burning may be obviated by leaving vacancies in the top mould; by placing patches of fresh cow-dung or decayed bark to receive the pots of seeds or plants; and by boring holes in the bed with a round pole sharpened at the end, which holes should be filled up with hay or dung when the heat is sufficiently reduced. Some persons place a layer of turf with the sword downwards between the dung and the mould: this but, if ever expedient, is only in late forcing; for in winter the full effect of a sweet well tempered heat is wanted, much of which, by being confined at top, may be forced out at the sides."

3204. *M'Phail*, in moulding common hot-beds, also raises hills in the centre of each light in the usual way. *(Gard. Remem. p. 51.)*

3205. *Nicol* gathers up from the surface of the beds a sufficient quantity of earth to raise hills whereon to stand the plants, in the middle of each light, about six broad at top, and within six inches of the glass. If the frames be of a proper depth, they should be twelve or fifteen inches high above the turf. *(Kal. 363.)*

3206. *Mills* puts under the centre of each light one solid foot of earth, the top of which is then within nine inches of the glass, and the top of the plants, when planted in it, will be within three inches of the glass.
3207. Planting out. Abercrombie, when the temperature is ascertained to be right, brings the plants in their pots; turns over the hills of mould, forming them again properly, and then proceeds to planting. “Turn those in pots clean out, one pot at a time, with the ball of earth whole about the roots; and thus insert one patch of three plants which have grown together, with the ball of earth entire, into the middle of each hill, earthing them neatly round the stems. Also any not in pots, having been pricked into the earth of the bed, if required for planting, may be taken up with a small ball of earth, and planted similarly. With water warmed to the air of the bed, give a very light watering about the roots, and shut down the glasses for the present, or till next morning. Shade the plants a little from the mid-day sun a few days, till they have taken root in the hills, and cover the glasses every evening with large mats, which should be taken off in the morning.”

3208. Nicol, before planting, if the beds have settled anywise unequally, rectifies and sets level the frames, by placing boards, slates, or bricks, under the low corners, so as to make them correct. He then makes up the sides of the bed with dung, a few inches higher than the bottoms of the frame; over these he lays some dry litter, or fern fronds, and planks at top to walk on. He then takes the pots of plants, each of which is supposed to have got two or three rough leaves, and making a hole in each full large enough to receive the balls, turns them out of the pots as entire as possible, placing them level with the surface of the hill, fitting the earth round their sides, and settling all with a little water. In the case of planting older plants than the above, at a farther advanced period of the season, or such as have quite filled their pots with roots, the balls may be reduced a little, and the fibres should be singled out, if anywise matted. But the above plants are supposed to have barely filled the pots with roots, and then the balls should be kept entire, that they may not receive a check in the transplanting.

3209. Temperature for fruiting plants. Abercrombie’s minimum is fifty-five degrees, and maximum in the day-time sixty-five degrees, the same as for the seed-bed.

3210. M’Phail says, “It appears, that during the winter and spring months, the medium heat of the air in the frames should be seventy-five degrees, and the medium heat of the mould eighty degrees. But when the sun shines, the heat of the air in the frames is often raised to a much higher degree; so that reckoning this heat, the medium for that of the air of the frames may be eighty degrees.” (Gard. Recov., p. 28.)

3211. Nicol’s medium heat for cucumbers is sixty degrees; in sunshine he admits as much air as will keep down the thermometer to sixty-five. (Kalend. p. 365.)

3212. Mils, in the fruiting-frames, wishes to “have at all times from seventy to eighty degrees of heat, which I regularly keep up by applying linings of hot dung, prepared one month previously, in the same manner as that for the beds. For the first month I cover the glass with a single mat only; and as the nights become cold, I increase the covering, using hay, which I put on the glass, and cover that with a single cloth, the temperature being then an adequate one. The heat of the glass is warm, which should be in two hours after covering up, a little air is required. When the glass and hay are warm, which is easily known by putting the hand under the hay on the glass light, the internal heat of the bed will be about seventy-eight degrees, in which degree of heat, the cucumbers show to the society have grown in length, in sixteen hours, one inch and a quarter. I give a little water round the insides of the frame as often as I find them dry, which causes a fine steam to rise, and I think it better than watering the mould, for if this latter practice is often repeated in winter, when the sun’s power is insufficient to absorb the moisture, and the glasses can but little open, to allow the damp to pass off, the earth, in a few weeks, will lose its vigor, and the roots of the plants will perish. Great care should also be taken, at this season, not to injure the roots by too much heat, which is not less detrimental than too much moisture; they can only be secured by keeping up a regular warmth, just sufficient to expel the damp which arises in the night from the fermenting dung.”

3213. Linings. The requisite degree of heat Abercrombie is careful to support in the bed, when declining, “by timely linings of hot fresh dung, which may be applied to the sides, fifteen or eighteen inches in width, and as high as the dung of the bed. Generally line the back part first, and the other in a week, or from ten days to a fortnight after, as may seem necessary by the degree of heat in the bed. Sometimes, if the heat is fallen abruptly below the minimum degree, it may be proper to line both sides moderately, at once, to recover the temperature sooner and with better effect: but be particularly careful never to over-line, which would cause a too violently renewed heat and steam in the bed. The dung for linings must be fermented, as in first building a bed.”

3214. Nicol, when the heat decreases, cuts away the old dung perpendicularly by the frame, and adds new linings (generally beginning with the back first), two feet broad, to the height of six inches above the bottom of the frame. As it will sink considerably in heating, he adds to it in a few days.

3215. Mils applies linings of hot dung prepared a month previously.

3216. Covering. This must be nightly performed till June; proportioning the warmth of the cover to the heat of the air in the bed, and that of the external air. Mats are laid next the glass; on these a layer of hay, and over this mats, made fast by boards, but not hanging over the linings, is the usual mode, early in the season. M’Phail says, “My method of covering up was as follows: In the first place, I laid clean single mats on the lights, in length and breadth, just or nearly to cover the sashes, taking care not to suffer any part of the mats to hang over the sashes on or above the linings, for that would be the means of drawing the steam into the frames in the night-time. On these mats was spread equally a covering of soft hay, and on the hay was laid another covering of single mats, upon which were laid two, and sometimes three or four, rows of boards, to prevent the covering from being blown off by the winds. The mats laid on next to the glass are merely to keep the seeds and dust which may happen to be in the hay from getting into the frames among the plants. If the bed be high in covering up,
steps or short ladders must be used by those whose office it is to cover and uncover; and great care must be taken not to break or injure the glass."

3217. Air. Abercrombie directs to "admit air every day, when the weather is moderate, without much wind; and always more freely in sunny days, than when cloudy and cold, or frosty. Open the lights behind, only a little at first, sooner or later in the day, according to the temperature of the season; increasing the opening, from about half an inch, to one, two, or three inches, or very little more; (decrease the opening occasionally, if the weather, in the early part of the season, changes very cold;) and shut closer in the same gradual order towards afternoon; generally shutting close in the evening, unless, in the early state of the bed, a considerable heat and steam continue. In this case, you may occasionally leave open about half an inch, hanging the end of a mat before each opening."

3218. M’Phail says, "A cucumber-plant delights to grow in a strong heat, and in sweet wholesome air; but if the air in which it grows be contaminated, unhealthy, or impure, the plant will not continue long in a healthy thriving condition. Whatever is disagreeable to the smell becomes in time hurtful to the cucumber-plant; therefore, whoever would wish to know if the air in a cucumber-frame or bed is of a healthy nature, only by putting their nose to it. He adds, in giving air and taking away the air, do it gradually, that is, by little and little at a time, which, without doubt, is the best way; for sudden changes are always attended with unpleasant consequences. A due proportion and continual supply of fresh air is at all times necessary, and more or less is required according to the heat of the linings, the temperature of the weather, and the thickness of the coverings put on at nights."

3219. Nicol admits air regularly in as large proportions as the state of the weather will allow; being careful to let off rank steam, if it abound, by leaving a till ( wedge), even in the night. My usual plan is to take off the lath and permitting the foul air to escape, in the winter months (that is, from the middle of November to the middle of February), is as follows: between eight and nine in the morning, I raise the lights, and let the confined air pass off, shutting them again; about ten I give a little air; at eleven more; at one I lower the lights a little, and between three and four I close them entirely. And two hours after the covering of the day has been put on, I give a little air for the night. Should the weather be changeable, the lights must be raised or lowered more or less, as circumstances may require; but some air about the times of the day above mentioned is absolutely necessary to keep the plants in a free-growing state."

3221. Water. Give necessary waterings, with water warmed to the air of the bed, mostly in the forenoon of a mild day, in early forcing; and in a morning or afternoon, in the advanced season of hot sunny weather. (Abercrombie.)

3222. M’Phail says, "The quantity of water requisite to be given to the plants depends upon the heat of the bed, the strength and age of the plants, and also on the temperature of the weather. When the weather is cold, wet, or gloomy, and the air moist, they require less water than when the weather is clear, and the air dry. If too much water be given, or the air be kept too damp, from setting and setting kindly; and if too little water be given, the plants will grow weak, and the fruit hollow. I seldom watered the plants with water warmer than 85 degrees, nor colder than 65; although, in general, I tried by the thermometer the warmth of the water I used, yet it is not necessary so to do. A good way to know if the plants require a watering, is to take a mouthful of it, and when it feels neither hot nor cold, then it is in a fit state for accelerating the growth of the plants, or for making them grow fast. I made it a constant rule never to water the plants but with clean sweet water; and if the water be clean and sweet, I am of opinion it makes little or no difference whether it be pump-water, spring-water, rain-water, or river water. Whatever water it is, it is of the best quality in water to bea sprinJan. 3186.); it is, however, necessary to add, that when the weather is very dry, it is advisable to give a water with a smell of earth, or put it in water of the earth."

3223. Nicol airs his water four by some means or other; waters once in two or three days after planting, and libers it in the watering-pot at the time of watering the plants, about or four or five o'clock, in order not to scorch the plants, which, he says, often happens when, after morning waterings, the sun's rays suddenly dart on the plants. (Kcl. p. 366. 385."

3224. Mearns, already mentioned (3160), uses water impregnated with sheep's dung, as does Knight. Mearns tried this water first 4th some cucumber-plants in the pine-stove, which had been planted in January, but which, in consequence of dull weather, had become weak, and of a pale green color; he applied the liquid to the roots, and in a few days a great change in the appearance of the plants was produced. Indeed, I consider it a hardy measure, the shorter the plants are, and the less the joints, and although the stove had scarcely any air given to it, yet the fruit swelled off rapidly, and attained a large size." These plants continued in bearing till May, and were then cut back to within six inches of the ground, when they started again with vigor. 4th No water was ever given over the leaves, but a continual supply of the liquid pigmented manure to the roots. (Hort. Trans. iv. 412.)

3225. Earthing. "Observe," says Abercrombie, "in proper time, when the first heat of the bed is moderated, to begin adding more earth between the hills, as the extending roots require to be covered, or the runners to be supported with mould; raising it by degrees equal with the tops of the hills, all in level order, from eight to ten inches thick." (Pr. Gard. p. 72.)

3226. Nicol, by the time the plants have sent out runners, and the roots spread quite over the hills, enlarges them; beginning by stirring up the earth in the other parts of the frame to its full depth with a hand-spade iron, breaking and breaking it if anywise caked by the heat. To this, add fresh mould sifted or finely broken, and in a dry state, so as to raise the surface nearly to the level of the hills; laying it in a sloping manner from back to front. Previously, he rectifies the position and level of the frames, and raises it so that the glass may be eight or nine inches above the mould in the centre. (Kcl. p. 367.)

3227. Training. To force the cucumber into early fruit, Abercrombie directs to "stop the runners as soon as the plants have made two rough leaves, as the bud that produces
the runner is disclosed at the base of the second rough leaf, it may be cut off or picked out, or, if the runner has already started, it may be pinched off close. This is called stopping at the first joint, and is necessary to promote a stronger stocky growth, and an emission of fruitful laterals; and from these, other prolific runners will be successively produced. The vines, without the process of stopping, would generally be both weaker, and so deficient in fertile runners, that they would sometimes extend two or three feet without showing fruit. When plants which have been once stopped, have extended the first runners to three joints without showing fruit, they are to be again stopped for the purpose of strengthening the plant, and disposing it for bearing. As fertile runners extend, train them out regularly along the surface, fastening them down neatly with pegs.

3229. M. Platc stops his plants when they have two joints; and "when the plants shoot forth again after the second stopping, they seldom miss to show fruit at every joint, and also a tendril; and between this tendril and the showing fruit may clearly be seen the rudiment of another shoot; and when the leading shoot has extended itself fairly past the showing fruit, then with the finger and thumb pinch it and the tendril off just before the showing fruit; and in pinching off the tendril and the shoot, the showing fruit is not injured. Thus stopping the leading shoot stops the juices of the plant, and in the means of enabling the next shoot (the rudiment of which was apparent when the leading shoot was stopped) to push vigorously, and the fruit thereby also receives benefit. When the plants are come into bearing, if the vines are suffered to make two joints before they are stopped, at the first of these joints, as I before said, will be seen showing fruit, a tendril, and the rudiment of a shoot; but at the second joint there is seldom to be seen either showing fruit or the rudiment of a shoot, but only a tendril and the rudiments of male blossoms. It is therefore evident, and but reasonable, that the shoot should be stopped at the first of these joints for female flower, the second joint, and so forward. For it is a well-known fact, that the vines would ever spring forth at the said second joint, but only a cluster of male blossoms or leaves, which would serve for no good purpose, but would rather exhaust the juices of the plant, which ought to be thrown into the productive parts of it. If the plants are suffered to bear too many fruit, that will weaken them, and cause the plants to be less prolific. The great rudiment of seeds, that is, the fruit, would not break forth, the numbers of fruit having deprived them of their proper share of the vegetative juices. The rudiments of some of the shoots may also be injured by accident, which sometimes prevents their proper development, and the losing of their full strength. When the fruit is rendered unfruitful, and therefore should be cut entirely off. In the course of the spring and summer months several shoots break forth here and there from the old ones. When too many break out, cut off the weakest of them close to the old shoots, and those which remain with regard to stopping, serve nearly in the same manner as young plants. If the old shoot from which the new one bursts forth, lie close to the mould, it sometimes sends forth roots from the same joint from which the young shoot proceeded, by which the young shoot is much invigorated, and the old plant, in some measure, renovated. When this young plant is fairly formed on the old shoot, it somewhat resembles a young plant formed and struck root on a strawberry runnit, and if the shoot were to be cut off on each side of the newly formed plant, and no part of the plants left in the frame but itself, by proper treatment it would soon extend itself all over the frame. In winter, when the plants are young, and before they come into bearing, it sometimes happens that they send forth too many shoots: in that case cut the weakest of them off, not suffering them to become crowded and thick of vines, for that would weaken and prevent the plants from bearing nearly as they ought to do. Keep the leaves of the plants always regularly thin. The oldest and worst of them cut off first, and cut them off close to the shoot on which they grow. This is necessary and right; for if any part of the stem of the leaf shoots be left, it would soon putrify and rot, and perhaps destroy by damp the main branch from which it proceeded."

3229. Nicol says, "Cucumber-plants will put out runners or vines, whether the heart-buds be picked out or not, which is a matter of trivial concern, although much insisted on by some, as being necessary to the enlargement of the crop. It is impossible to discover any advantage, apparent or otherwise, made the comparison in the same bed, which otherwise of course could not be fair. When the vines have grown to the length of four or five joints, and fruit appear on them, they may be stopped at one joint above the fruit; but otherwise they may be allowed to run to the length of seven or eight joints, and may then be stopped and will generally form good large fertile shoots. These should be regularly spread out, and be trained at the distance of eight or ten inches part."

3230. Upright training. "Cucumber-plants being climbers by means of their tendrils, some branchy stems being placed to any advancing runners, they will ascend and produce fruit, at a distance from the ground, of a clean growth free from spots, and well flavored."

3231. Setting the fruit. "The cucumber," Abercrombie observes, "bears male and female blossoms distinctly on the same plant. The latter only produce the fruit, which appears first in miniature, close under the base, even before the flower expands. There is never any in the males; but these are placed in the vicinity of the females, and are absolutely necessary, by the dispersion of their farina, to impregnate the female blossom; the fruit of which will not otherwise swell to its full size, and the seeds will be abortive. The early plants under glass, not having the full current of the natural air, nor the assistance of bees and other winged insects to convey the farina, the artificial aid of the cultivator is necessary to effect the impregnation. At the time of fructification, watch the plants daily; and as soon as a female flower and some male blossoms are fully expanded, proceed to set the fruit the same day, or next morning at furthest. Take off a male blossom; detaching it with part of the footstalk. Hold this between the finger and thumb; pull away the flower-leaf close to the stamens and anthera or central part, which apply close to the stigma or bosom of the female flower, twirling it a little about, to discharge thereon some particles of the fertilising powder. Proceed thus to set every fruit, as the flowers of both sorts open, while of a lively full expansion; and generally perform it in the early part of the day; using a fresh male, if possible, for each impregnation, as the males are usually more abundant than the female blossoms. In consequence, the young fruit will soon be observed to swell freely. Cucumbers attain the proper size for
gathering in about fifteen, eighteen, or twenty days from the time of setting; and often in succession, for two or three months or more, in the same bed, by good culture. The above artificial operation will be found both necessary and effectual in forcing the cucumber, between the decline of autumn and May, while the plants are mostly shut under glass. To plants more freely exposed to the free air, in the increasing warmth of spring, and in having the full open air in summer, from June or July till September, the impregnation is effected mostly or wholly by nature. The male flowers, being by some ignorantly denominated false blossoms, are often plucked wholly off as useless, under a notion of strengthening the plant: but this should not be generally done. Where crowded too thick in clusters, some may be thinned out moderately; but their agency being absolutely necessary in fertilising the females, they should only be displaced as they begin to decay, except where they are superabundant.”

3292. M'Phail observes, “It is the female blossoms or flowers that bear the fruit; but if they were not to be impregnated by the male flowers, they would prove barren and unfruitful. The female blossoms are easily to be distinguished from the male ones, for the rudiment of the fruit is apparent at the bottom of the female flowers, and the flowers have no stamens, but have three small-pointed filaments without summits: whereas the male blossoms have not any rudiment of fruit about them, but in the centre of the flower are three short stamens, which are inserted in the impalement. When the female or fruit blossoms are in full blow, take a male blossom which is in full blow, and holding it in one hand, with the other split, and tear off the flower-leaves or petals, taking care not to hurt the stamina or male part. Then hold the male blossom thus prepared between the finger and thumb of the right hand, and with the left hand gently lay hold of the female blossom, and holding it between two fingers, put the prepared male blossom into the centre of the female blossom, and there the farina, pollen, or dust of the anthera, clings or sticks to the stigma, and thus the impregnation of the fruit is effected, and the plants are thereby rendered fruitful, which, being in frames in a climate by art made for them, would otherwise in a great degree be rendered barren and unproductive; and which I have frequently known to have been the case, even when at the same time the plants were in a vigorous flourishing state. Generally leave the prepared part of the male blossom in the centre and take a fresh male blossom to every female blossom. But if male blossoms run scarce, which seldom or never happens, make one male blossom do for two or three female ones.”

Nicoll states, that cucumbers will grow and will arrive at full size without the female flowers being impregnated; the seeds, however, will prove abortive. The directions he gives for impregnating are in substance the same as those of M'Phail. The fruit being set and swelling, some lay fragments of glass or slate beneath it, in order to keep it clean, and to admit as much air and light as possible to the under side, so as to cause its approach in greenness to the upper.

3294. Gathering the crop. Cucumbers are used green or unripen, and before they have attained their full size. They are cut and gathered when four, five, six, or eight inches long, according to the kinds. To this size they attain in ten days, or a fortnight, in the best part of the season.

3295. To save seed. “Select some best summer fruit, from good productive plants; which permit to continue in full growth till they become yellow. Then cut them from the vine, and place them upright on end, in the full sun, for two or three weeks; when they may be cut open, and the seed being washed out from the pulp, spread it to dry and harden: then put it up in papers or bags for future sowing. It will remain good many years: and seed of three or four years’ keeping is preferable for early frame crops.

3296. Cultivation of the cucumber in a flued pit. Nicoll says, “Those who would have cucumbers on the table at Christmas, (a thing sometimes attempted,) will find it more practicable, and less troublesome, if the plants be grown in a flued pit, in the manner of late melons, than if they grow on a common hot-bed. In this case the cucumbers should take place of the melons planted in this compartment in July, and which will, by the middle or end of the month, have ripened off all their fruit of any consequence.

3297. Sow the seeds of some of the early sorts (those best for early being also best for late), “in small pots, about the first of July, and place them in the pit along with the melons, or under a hand-glass on a slow dung-heat; where let the plants be nursed, and be prepared for planting about the second or third week in the month. Observe to sow old seeds, not those saved this season, which would run more to vines than to fruit. Let the pit be prepared for their reception, by trenching up the bark or dung, and by adding fresh materials, in so far as to produce a moderate growing heat; observing the directions given for preparing the pit for the melons in July, and in the same manner, except that the earth may be put over, to the depth of a foot or fourteen inches. The plants may be placed closer in planting them out, than is necessary in a spring hot-bed. They may be planted at the distance of a yard from one another, and rows lengthwise in the pit. If they will in time be made large, they should be moderately supplied with water once in four or five days, and should always be watered over the foliage; the more especially when strong fire-heate becomes necessary, as cucumbers naturally like a moist rather than a dry heat. The temperature should be kept up to about 64 or 65 degrees in the night, and 75 in the day, and by making it (however warm it may otherwise be) the weather will allow; and so as to keep the mercury down, in sunshine, to about 70 degrees. The plants will require little other pruning than to stop the vines, as they show fruit, at a joint or two above; do not push them through the chamber shoots. Observe to pick off all damped leaves as they appear; and otherwise carefully attend to them, as above directed, while they continue to flourish, or to do any good worthy of such attendance.”

3298. Cultivation of the cucumber in M'Phail's brick-bed or frame. “When I used,” observes M'Phail, “to cultivate cucumbers on a dung-bed, the fruit were sometimes watery and ill-tasted; but after I began to cultivate them on a brick-bed, the fruit were constantly firm and well-flavored; which is certainly occasioned by the goodness and wholesomeness of the food with which the plants are fed or nourished.” Besides this objection, M'Phail mentions several others, the principal of which are —
The risk of burning the plants at first, as well as on the application of every fresh lining. In a few days after a cucumber-bed has been planted, the heat of the dung begins to decline, and perhaps the whole bed is made hot, wet, and gloomy; and in that case a lining of fresh dung is not only desirable, but indispensable. If the steam of the linings get in, it will hurt the plants: and if there be any thing which smells disagreeably in the mould, or underneath the mould in the frames, the linings will cause unhealthy effects. There is no doubt that, if the steam in time will prove too great for the plants. So that, there may be a degree of heat in the frames strong enough for the growth of the plants yet, through means of that heat, something may arise in the frames which will become progressively, if not instantly, destructive of the plants, especially when they are young and tender. Care, therefore, must be taken that nothing be introduced into the frames among the plants but what is of a sweet wholesome nature.

The difficulty of keeping up the proper heat in winter.

The great attention and expense attending the formation and general management of dung-beds in winter.

3239. The chief advantages of Mr. Phail's frame are stated to be:

That the coldest place in the bed is exactly in the centre of each pit, from which centre the heat increases on each side to the linings where the heat begins. The plants being planted, he says, in this centre, or coldest part of the bed, their roots can never be hurt by the heat increasing on each side gradu- ally. Full advantage is thus made of the increase and continuous heat of the steam. The heat in the centre of the pit, just where the plants are first planted, seldom rises higher than to about eighty or eighty-five degrees, nor does it ever rise higher in any part of the pits than about ninety-six or ninety-seven degrees; nor do I believe it can ever be raised higher than this. In the summer, the plants will prove to them, and, in winter, the heat will get into the plants. So that, if the heat of the framed bed, under the mould in which the plants are placed, frequently rises to above 120 degrees, when, at the same time, the air in the frames can scarcely be kept up to a proper degree of heat; this: frequently happens in cold weather in winter. The scorching heat of the hot-house, or horse-dung, when too hot for plants, is equal to 120 degrees or more, and heretofore is probably the heat of blood in fevers.

The dung requires no more working than what is necessary to bring it to and keep it in a proper degree of heat, and to let some of its more rank qualities pass off by evaporation; and as soon as the heat rises in the linings, it circulates in the flues, and warms every part of the bed; whereas the dung for making a common cucumber-bed must be turned and worked, and lie, till, by fermentation, its rank qualities be evaporated, and its violent heat be somewhat diminished. This, as already noticed, is a very great advantage.

The linings retain the heat longer than the linings of a dung-bed do, and that because the flues are constant full of steam; but a dung-bed having little or no vacuity for the retention of the steam, the steam of the linings of it is perhaps more immediately evaporated, and consequently the heat of the linings is sooner exhausted than the heat of the linings of the brick-bed.

In the course of the winter a dung-bed sinks so low, that it becomes difficult sometimes to get a proper heat raised in the linings; but my brick-bed being always of the same height, such difficulty can never happen.

A brick-bed may be built and set to work immediately; the heat of the linings will dry the lime of the joints of the bricks. The evaporation in the frames, from the moist lime of the joints of the brick-work, has no bad effect on the plants; but when a bed is set to work before it be dry and steady, great care must be taken not to injure the brick-work in filling up the pits.

A brick-bed is not so much filled as a dung-bed is; and the flues being made perfectly close, no tainted or bad-smelling air can get through them into the bed, so that it is of little or no concern whether the dung of the linings be sweet or otherwise, or whether the linings be made of dungs, or of any thing else, provided there be a sufficient heat kept in them, and no pernicious steam be drawn in among the plants by the current of air.

3240. The plan of Mr. Phail's frame has already been given and described. (1551. and fig. 233.) It is almost needless to repeat that a sheltered dry situation for placing it is of the first consequence. The bed being built, "when the frame is about to be set upon it, a layer of mortar is spread all round upon the upper course of brick-work on which the bottoms of the frames are to rest. Thus the frames are set in mortar on the bricks; and the flues are, with a bricklayer's brush, well washed, and rubbed with a thick grout made of lime and water, which stops every crack or hole, and prevents the steam of the linings from getting into the frames. This washing of the flues I had done once a-year, for no crack or hole must ever be suffered to remain unstopped in the flues. I found little or no trouble in keeping the flues perfectly close, nor is it indeed likely that they should become troublesome if the bed stands on a sound foundation, for the heat of the dung has not that powerful effect on the flues, as fire-heat has on the flues of a hot-house; because the heat of dung is more steady, and not so violent as the heat of fire; and besides, the flues of the cucumber-bed are almost always in a moist state, which is a preventive in them against cracking or rending. When the bed is first built, the pits are about three feet in depth below the surface of the flues. These pits I had filled up about a foot high, with some of them with rough chalk, some of them with small stones, and some of them with brick-bats: this is to let the wet drain off freely from the mould of the beds. After this filling up with chalk, stones, and broken bricks, there is a vacancy in the pits about two feet deep below the surface of the flues; this vacancy I had filled to a level with the surface of the flues with vegetable or leaf mould; and in putting it in, it was gently pressed, to prevent it from sinking too much afterwards."

3241. "On the surface of the mould with which the pits were filled, "under the middle of each light, and
which is just in the centre of the mould in each pit, make holes of mould in the same form as is commonly done on a dung-bed. These holes are to set the plants in, and are to be raised at first nearly close to, or with their bottoms just upon the surface of the glass. They are to be filled with the mould, and watered plentifully, until the surface is wet, with the exception of the sinking of it; for as the frames are set on bricks, they cannot sink, but mould newly put in is sure to settle, and the measure of settlement will ever depend upon the lightness and texture of the mould with which the pits are filled. Therefore, these and such like matters must be left to the discretion of those who have attended upon the setting in; they will know how to judge whether the surface be covered, and ready for the reception of the plants, if the flues be strewed over with mould, so that their surface be just covered, to a stranger it is altogether a deception, for in every respect it has the appearance of a dung-bed."

2342. **The sashes of the frames** "which I used were glazed in lead; but if any person who rears early cucumbers have lights which are not glazed in lead, but are slate-glazed, the vacancies between the glass had best be filled up close with putty, to prevent too much air from getting into the frames in the cold days in winter. These frames under my present management were glazed with lead, and never need new glass every year. This method, I am clearly of opinion, is more profitable than if the frames were neglected for two or three years, and then have a thorough repair with two or three coats of paint. When frames are new painted, they should be suffered to lie and sweeten for some time, at least for two or three weeks, or until they are sweet and dry. They are then to be polished and painted in several coats, if they are to be made nearly three feet broad in their foundation, and tapered up to about thirty inches at the top, by which they will retain their heat, and in sinking will close to the bed, which is what should at all times be paid proper respect."

2343. **Linings of the frames** "The linings are to be applied to the bed a few days before the plants are ready for finally planting out, in order that the mould and every thing in the frames may be properly warmed for their reception. The dung of which the linings are to be made may either be cast together in a heap, to bring it to a heat before it be laid round the bed, or it may be laid round the bed as it is brought from the dung-yard, but whichever of these methods be taken, when the linings are making up, the dung should be well shaken, and laid up lightly, so that the heat of it may come up freely. As it takes some days before the linings are able to warm the earth in the bed sufficiently for the reception of the plants, the rank steam of new dung-linings is very useful. The principal dung that is carried in hedges is to be brought in as much, and no more, than can be made nearly three feet broad in their foundation, and tapered up to about thirty inches at the top, by which they will retain their heat, and in sinking will close to the bed, which is what should at all times be paid proper respect."

2344. **Refilling the linings** "As the linings sink they are to be raised with fresh dung; but they should seldom be raised higher than about the level of the mould in the frames in which the plants grow, especially when there is a strong heat in them; for, when there is a great heat in them, if they are kept higher than the level of the mould, through the dung they dries the sides, and the steam if it can be made to sink much below the level of the mould in the frames; for that, on the contrary, would cause too much moisture in the frames, especially in the winter and spring months. When the heat begins to be too little, notwithstanding the linings being kept to their proper height, the fresh unexhausted dung on top of them in the frames should be covered with dung and advisable to be renewed as often as the heat will and that which was laid aside in the foundation, and fresh dung laid above it in lieu of which that was carried away."

2345. **Renewing the linings** "Both the side linings may be raised at one time, but both of them should never be renewed together; for if both were to be renewed at the same time, it would for a time cool the frames too much, and when the heat of both came to its full strength, it would probably be too powerful for the roots of the plants when extended to the flues. I seldom or never renewed the end linings, because I found the heat of the sides cools fully as fast, for as it leaves the frame or vacuum in every part of the bed, the steam being fluid, circulates in, and warms every part thereof. And for the very same reason there is no occasion for having a strong heat in both the side linings at one and the same time, except in very cold weather. In making up and pulling down the linings, care should be taken not to injure the brick-work."

2346. **The covering the linings in the winter and spring** is absolutely necessary; "for, notwithstanding the heat of the linings, it would be impossible to keep up a proper degree of heat in the frames for the plants without it. When therefore the cutting up in the evenings and uncutting up in the mornings, must be particularly attended to, and more or less put on according to the heat of the linings and the temperature of the weather."

2347. **After the bed is set to work**, heat and sweet moisture are the two principal agents required for promoting the increase and vigor of the plants; "therefore it is necessary to have an amount of heat enough to keep the heat in the centre of the mould fluctuating between 80 and 90 degrees, cold water may be poured on the flues twice or thrice a week. There is no danger of creating damps or impure air in the frames by watering the flues; for the water is no sooner poured on them, than it runs down their sides, and passes through the brick frames; and the external heat of the bricks is conveyed to the flues, gives only a momentary check to the heat of the frames; for the flues being at all times full of hot steam, when the watering is finished, the heat quickly resumes its former vivacity, and raises a warm vapor in the frames, well adapted for promoting vegetation, and in increasing the growth, and invigorating the plant in all its parts. The mould round about the sides of the pits close against the inner sides of the flues, should be kept nearly on a level with the surface of the flues; and as it is the mould that joins to the flues which receives the first and greatest heat from the linings, it should continually be pulled up; for if any danger is taken against the flues be suffered to become dry and husky, air will be generated in the frames disagreeable to the plants."

2348. **Temperature of McPhail's frame.** McPhail has, in his gardener's Remainder, as well as in his _Treatise on the Cucumber_, given the temperature of one of his beds for every day in the year, in which the cucumbers are grown: Here are only very interviews. By the heat described in this table, and plenty of water, the cucumber-plant the seeds of which were sown on the 22d day of October, were maintained in a healthy state, in this frame, from the month of January to the beginning of December. The melon-plants were kept in about the same degree of heat given for the culture of the cucumbers; and for a few weeks before the fruits were formed, that if any person keep melon or cucumber plants in nearly the same degree of heat as are set down in the table, and by the latter part well in other respects, the way to do which has been clearly pointed out, they will not fail of having success. McPhail adds, that notwithstanding the objections of some who have been successful in making trial of his bed, it is now generally approved of, and in practice by numbers of the best gentlemen's gardeners in the kingdom; and by various market-gardeners in the neighborhood of London.
In all other respects, the culture of the cucumber or melon, on McPhail's brick-bed, corresponds with the culture of these fruits on common dung-beds.

3249. The cultivation of the cucumber in West's frame (fig. 290.), differs from the common mode; but it being attended with less risk, in our opinion, this frame or pit is superior to McPhail's, as requiring much less dung, presenting a much more neat and orderly appearance, and giving a greater command of temperature.

3250. Cultivation of the cucumber in a common pit without flues. Some form a narrow dung-bed along the middle of such a pit, leaving room for adding a lining on each side when the heat declines. This method succeeds very well late in the season; but at an early period the sinking of the bed from the glass leaves the plants at a great distance from the light.

3251. Cultivation of the cucumber in stoves. "Cucumber-plants," McPhail observes, "will grow in a hot-house where the pine-apple is cultivated; but they will not be very long-lived there, for that is not a healthy climate for them." In August, sow the seeds in boxes filled with vegetable or other light earth, and place them on shelves in the back side of the hot-house, where the sun may not be interrupted from flashing on them in the short days. They may, perhaps, produce a few fruit in the month of December or January. (Gard. Rem. p. 301.)

3252. Akeronomes says, "Some gardeners, ambitious of early fruit, try a sowing in the stove under the disadvantages of December. For fruiting this plant in the house, narrow boxes, three feet long, and full twenty inches deep, may be found more commodious than pots. The boxes may stand upon the crib-trellising over the flues, or be suspended near the back wall eighteen inches from the upper tier of lights, so as not to shade the regular house-plants: this is the best situation for a very early crop. The plants may be originated in small pots, plunged into the bark-bed, in order to be transplanted with a ball of earth. Those who aim to have fruit at Christmas, introduce seedlings about the middle of August. The chief deviation from the course of the hot-bed is, that the plants must be trained in the house, those two for which purpose form a light temporary trellis of lathes. Give water every other day at least." (Pract. Gard. p. 618.)

3253. Allton's method of raising cucumber-plants in August, with a view to their being fruitful in the stove through the winter, has been already given. (3174.) We now subjoin the remainder of that excellent paper.

3254. Cucumber-plants being raised on a well-prepared one-light hot-bed; when the cotyledons or seed-leaves became nearly of full growth, the plants were potted out two into each pot, known to gardeners about London by the name of upright thirty-two. When these pots became filled with roots, the plants were again shifted into larger ones, called sixeens, and removed from the seed-bed into a three-light frame, in a smaller — but allow a considerable portion of air being given day and night, both in the front and back of the frame. About the middle of September, the plants having again filled their pots with roots, and become stocky, were taken from the frame to the stove, and after a few days received the last shifting into larger pots of the following dimensions: — at the top fourteen inches deep, the bottom ten inches across, and twelve inches deep, all inside measure; each pot at equal distances apart, having three side drain-holes near the bottom, and a larger one in the centre of the bottom, and containing about three pecks of solid earth.

3255. The plants were trained in a pinery. On the front edge of the back flue of this stove, a fascia-boarding, six inches deep, was affixed, the whole length of the building, forming all along a trough or enclosure for a reserve of compost after the exhaustion of the mould in the pots had taken place. The pots were now placed in regular order upon the mould-trough over the flue, at three feet apart, and remained in this situation throughout the winter, and till the second sowing was placed upon the end flues of the house; underneath each pot was set an upright circular garden-pan, six inches deep, and fourteen inches diameter, which being filled with earth, the pots were plunged therein about two-inches deep, and from thence, the drain-holes being sufficiently covered with mould, served as outlets to the roots.

3256. Temperature. The fire-heat of the stove was kept day and night at sixty to sixty-five degrees Fahrenheit's thermometer, varying only a few degrees when the sudden influence of sun or steam produced an additional glow of climate. The plants being now established and vigorous, required stopping for latitude; the second and third latits. shoots, in their turn were stopped also, and the blossoms from time to time set, as usual, for succession of supply.

3257. Waterings were necessary only when the surface of the earth was evidently dry, and light sprinklings of soft water, tempered in the stove, were occasionallly given over the leaves of the plants and path with good effect.

3258. Steam from a well regulated flue was considered always favorable to the cultivation, but applied sparingly on account of its scalding effect upon the leaves when the vapor proved over-heated.

3259. Diseases and Insects. For the mildews, flower of brickstone, colored leaf-green by a little soot, has been applied with the best success in all stages of the disease, and copious fumigations of tobacco were used for the destruction of the several species of the aphid tribe.

3260. Result. Under this simple practice, winter cucumbers have been produced abundantly in the months of November, December, and part of January, in all the royal gardens of His Majesty during a series of years.

3261. Cultivation of the cucumber in Weeks's patent frame. (1583.) We know only of two instances in which this ingenious invention has been tried, both of which are mentioned at the end of Weeks's Forcer's Assistant. The chief objection to the plan, is that the bed or stratum of earth in which the plants are grown being but of moderate depth, and surrounded by air above and below, is extremely difficult to retain at an equable moisture.

3262. Growing the cucumber under hand-glasses. The following method is given by McPhail as that generally practised: "The seeds are sown some time about the middle of April in a cucumber or melon bed, and when they come up, they are potted out into small pots, two or three plants in each pot, and are kept properly watered, and stopped at the first or second joint. About the middle of May, a warm situation where the mould is very rich is pitched on, and a trench is dug out about two feet deep, three feet broad, and the length is proportioned according to the number of lights it is intended for. This trench is filled with good warm dung, and when the dung is come to its full

P 2
heat, it is covered over with eight, ten, or twelve inches deep of rich mould. The glasses are then set upon it about three feet distant from each other, and when the mould gets warm under them, the plants are turned out of the pots with their balls whole, and plunged in the mould under the glasses, and a little water given them to settle the mould about their roots, the glasses set over them, and after they have made roots, and begin to grow, in fine days they are raised a little on one side to let the plants have the free air; and as the weather gets warmer and warmer, air is given more plentifully, to harden the plants, so that they may be able to bear the open air, and run from under the glasses. When the plants begin to fill the glasses, they are trained out horizontally, and the glasses are set upon bricks or such like, to bear them from the plants. After this the plants require nothing more but to be supplied with water when the summer showers are not sufficient, and to stop them when they run too thin of branches, and thin them of leaves or branches when they are likely to become overcrowded. In warm summers and in warm situations, by this mode of management, the plants will bear plentifully for about two months, provided they be not attacked by insects or weakened by diseases."

3563. Abercrombie describes a practice somewhat different, but with his usual attention to detail and order. He says—To have a general summer crop, to fruit in hot-bed ridges under hand-glasses, sow some seed of the long prickly kind in a hot-bed, under a frame or hand-glass, or in any cucumbers hot-bed in cultivation, about the middle of March, or thence till the middle of April. When the plants have been up three, four, or five days, prick out in the same another hot-bed, three or four inches asunder. A portion may be put in small pots, three plants in each, and plunged in the bed. Give water, and shade from the sun, till they take root; and manage as for the frame-crop. In three or four weeks, when advanced in the first rough leaves, about two inches broad, and stopped at the first joint, as directed in the common pots, sow two glasses, such as are transplanted into ridges, under hand-glasses, to remain for fruiting. The period for this may fluctuate from the middle of April to the beginning of May.

3564. Having a sufficient quantity of prepared dung make a hot-bed on the level ground, three feet and a half or four feet wide, and two and a half high, the length as required, according to the number of hand-glasses intended. Earth it at top, six or eight inches thick, and place the hand-glasses along the middle, at three feet and a half distance. Sometimes the bed is made in a moderate trench, twelve or fifteen inches deep, in some good soil in the kitchen-garden, in order to have the excavated earth of the trench ready to use for moulding the bed. When the earth under the glasses is warm, proceed to put in the plants, removing them from the nursery-bed, with as much earth as will adhere about the roots. If you have any plants in small pots, turn them out with the balls entire, and plant three plants under each glass, watering; put in the glasses; make the glass, and then take root; after which, let them enjoy the sun and light fully, only covering the glasses and bed every night with mats till June, or commencement of warm weather. Admit air every mild day, by propping up the southern side of the glasses one or two inches; moderate waterings will be necessary twice a week or oftener.

3565. As the plants push runners of considerable length, train them regularly. When extended to the limits of the glasses, and when the weather is settled warm, about the beginning or middle of June, they should be raised upon three props, two or three inches high, and the runners trained out in regular order; but cover them in cold nights with mats, for the first week or two. Continue the glasses, and circumspectly water in dry weather, as may be necessary; the plants will produce fruit in June, July, August, &c. in plentiful succession.

3566. In default of plants raised in a previous nursery-bed for transplanting, sow seed under the hand-glasses in April or in May, inserting several seeds in the central part under each glass. When the plants have been up a few days or a week, thin them to three or four of the strongest in each patch, managing them afterwards as the others. They will come into bearing towards the end of June or July, and thence till September.

3567. Should there be a scarcity of dung to make a regular bed, in the last week of April, or in May, you may dig circular holes two feet wide, a space deep, and four or five feet asunder; fill them with hot-dung, thoroughly mixed and earthed over; then sow them in the same manner as the put either plants or seed; and place on the glasses: the plants will produce fruit in June or July till September.

3568. In default of hand-glasses: make a hot-bed, or holes of dung, as above, in May: put in plants or seed, and defend with oiled-paper frames to remain constantly, day and night, till settled warm weather in June or July. Give the additional protection of mats over the paper frame in cold nights and bad weather.

3569. In the culture of all the crops, give proper supplies of water in dry warm weather, two or three times a week, or every day in the hottest season of June, July, and August. In the hot-bed ridges make the above ground in April or May, in three or four weeks or more after making the heat be much declined, and the nights, or general season, remain cold, let a moderate lining of hot-dung be applied to the sides; which will both throw in a reviving heat, and widen the bed for the roots and runners of the plants to extend. (Abercrombie.)

3570. Insects and diseases. The thrips sometimes attacks early cucumbers, and is to be destroyed by fumigation. The red spider rarely makes its appearance; when it does, water must have been improperly withheld. Some soils produce canker in the shoots, especially where they branch from the main stem. When this is the case, the only resource is to renew the soil and the plants.

Sect. VII. Of the Culture of the Melon.

3571. The melon requires the aid of artificial heat the greater part of the year, and even in the warmest months it cannot be brought to perfection without the protection of glass. Its culture is an object of emulation among gardeners; and the fruit of the best sorts have a peculiarly rich flavor, thought by some to bear some resemblance to that of the pine. Ripe fruit, Abercrombie observes, "may be had by forcing at any season; but the main crops raised for the general demand, are seldom cut, at the earliest, before May, and the last succession mostly ceases to yield fruit after October." To ripen the
CULTURE OF THE MELON.

best, largest, fine kinds, M'Phail observes, "as great an atmospheric heat, and a bottom heat to its roots also, is required as is sufficient to ripen the pine-apple in this country; but as the melon is produced from an annual plant, the seeds of which must be sown every year, it requires a different mode of culture. Different methods of treatment and various kinds of earths and of manures have been recommended, and used successfully in rearing of melons. The great thing after planting is to give them plenty of atmospheric heat, and a sufficiency of external air and water. Those methods which are most simple and the least expensive, and best calculated to assist in making a suitable climate for the melon-plant to grow in and ripen its fruit well, should be preferred."

3272. Soil. Abercrombie says, "The melon will succeed in any unexhausted loam, rich in vegetable rudiments, with a mixture of sand, but not too light. The following is a good compost: two thirds of top-spit earth from a sheep common, adding sharp sand, if the earth contains little or none, till half is sand; one sixth of vegetable mould; and one sixth of well consumed horse-dung. Or, if the earth is not obtained from a pasture, rotted sheep-dung may be substituted for the last. The ingredients should have been incorporated and pulvcrised by long previous exposure and turning over. The compost should be dried under shelter before it is used, and warmed in the frame for potting."

3273. M'Phail says, "Melons will grow and produce fruit of a good flavor, if they be planted in any kind of earth not too light a texture, whether it be taken from a compartment of the kitchen-garden or from a corn-field mixed well with good rotten dung; but earth of a loamy nature is the best, because it retains moisture longer than light earth. Earth dug from the surface of a common, where sheep and cattle have long been pastured, is excellent for the melon. It should be broken well, and lie a few days before it be used; and if it be exposed to a winter's frost, it will do it good. This sort of earth, if it be taken from the surface of the common, will require no manure the first year of using. I would here mention, that unless the earth which I used for the melon-plants was very strong, I made it a practice, when the melons were wholly earthed up, to tread the surface all over, which makes the earth retain its moisture longer than if it were left loose."

3274. Nicol says, "Soil for melons may be thus composed: one half strong brown loam from a pasture; a quarter light sandy earth; an eighth part vegetable mould of decayed tree-leaves; and an eighth part rotten stable-yard dung. The mould for melons should be well incorporated; should be exposed to the frost, and be frequently turned over to meliorate."

3275. Sorts. The following list is given by Abercrombie: —

| Netted cantaleupe, large round          | Scarlet cantaleupe       | Oblong, smooth-rinded   |
| Early small black rock cantaleupe      | Silver cantaleupe        | Round, smooth-rinded    |
| Constricted rock cantaleupe, cheese-   | Silver, smooth-rinded    | Round white-rinded      |
| shaped                                 | Larger netted romana, oval | Green-fleshed           |
| Green cantaleupe (oblong rock)         | Polignac                 | Water-melon, a very large roundish green fruit. |
| Orange cantaleupe                      | Musk, or oblong ribbed, netted-rinded |                        |
| Early golden cantaleupe                |                         |                        |

3276. Nicol enumerates the following, in the order in which they ripen: —

| The early golden cantaleupe            | The silver cantaleupe    | The black rock cantaleupe | Lee's rock cantaleupe |
| Orange cantaleupe                      | The green cantaleupe     | The carbnuedrock          | Lee's romana          |
| The netted cantaleupe                  |                         | Large netted romana       | Fair's romana         |

3277. Estimate of sorts. "The cantaleupes are in high estimation for their general superior flavor, although not uniformly such great bearers as some others in the list; they are besides admired for their handsome and curious shapes, some of them growing very large. The netted cantaleupe is a good bearer; the fruit above the middle size, round, heavy, full of juice, and high flavored. The early small black rock cantaleupe is a good bearer: but there is a large black rock which holds an inferior rank, both for bearing and the flavor of the fruit. Of the carbnuedrock there are two sorts: the smaller is by far the best. The green cantaleupe has a dark green rind, with a pale pulp, grows rather larger than the early black rock, and vies with it in flavor. The orange cantaleupe is an excellent early variety, a great bearer; the fruit under the middle size, but juicy, and of the most generous flavor. The early golden, and the prolific, set speedily, and soon ripen; the fruit middle-sized, the flavor not so elevated as might be expected from a cantaleupe. The silver cantaleupe bears freely; the fruit middle-sized, and for flavor ranking with the finest. The small romana is one of the most plentiful bearers, either for an early or main crop; the fruit not abundantly juicy, but good-flavored. The larger netted romana bears more freely than large sorts in general; the fruit is substantial and heavy, a single melon sometimes weighing ten pounds, not so juicy as the best cantaleupes, but the flavor high and grateful. The polignac is also a rich-flavored fruit. The old oblong-ribbed is generally a good bearer, and the fruit agreeably flavored. The other kinds also will ripen here in good perfection, except the water-melon, which does not always ripen freely with a good full flavor. The principal culture, however, the cantaleupes, romanas, and polignac, are indisputably preferable: any of the others may be adopted in secondary crops, or for variety."

3278. M'Phail says, "Several sorts of melons are not worth propagating, that is, in the estimation of some persons; but there are some kinds of them, such as the early cantaleupes and the rock cantaleupes, which, when well ripened, are delicious in flavor, and very wholesome in quality. Of the varieties, there are those called the rock cantaleupe, the early small black, large black, the orange, the golden, the silver, the green, the carbnuedrock, the netted, the Roman, the musk, and the scarlet cantaleupes, and likewise the oblong-ribbed, the smooth-rind, the round white, the green-fleshed, the water-melon &c."
3279. Time of beginning to force. From the time of sowing, ripe fruit may be cut in about fifteen weeks, as an average period: when many short and wintry days fall in the course, it may last eighteen weeks; but when the forcing is not commenced till the days are nearly twelve hours long, and continually lengthening, ripe fruit is sometimes cut in ten weeks. The period also depends upon the sort. Little time is gained by beginning excessively early. The early and main crops are commonly originated from the middle of January to the first week of February; the latter or succession crops, at the beginning of March; and late crops intended to fruit at the end of summer, in the middle of April.

3280. M'Phail and Nicol sow in January. The latter says, "I formerly cut melons, for three years successively, on the 15th, 12th, and 10th of May, and never sowed before the last week of January, or first of February. In 1788, when at Rainham Hall, in Norfolk, I sowed melons on the 12th March, and cut ripe fruit on the 50th May. The kind was the early golden cantaloupe. This shows how little is to be gained, or rather, how much may be lost, by early forcing.

3281. Forming the seed-bed. The plants may be originated in a cucumber-bed, and this is the general practice; but Abercrombie prefers a separate bed, built a slight degree higher than that for the cucumber, at the same season, and adapted to a one or two light frame, according to the quantity to be raised. Nicol raises the melon almost exactly in the same way as the cucumber, and there is very little difference in his subsequent culture of these plants.

3282. Choice of seed. "Seed under the age of two years is apt to run too much to vine, and show only male flowers; but new seed may be mellowed by being carried in the pocket a fortnight or more, till the heat of the body has dried and hardened it. Seed, twenty years old, has been known to grow and make fruitful plants; but seed, which has been kept three or four years, is quite old enough, and less likely to fail than older."

3283. M'Phail says, "It is best not to sow melon-seed till it be two or three years old. It cannot be too old if it be sound and grow well. Young seed is apt to run too much to vine, and to show more male than female blossoms."

3284. Nicol says, "I have sown melon-seeds twenty years old, from which I have raised very healthy and fruitful plants." (Kat. p. 396.)

3285. Miller and Nicol say, young melon-seeds may be sown in the pocket, near the body, for several months previous to sowing, which has the effect of fully maturing them. "If seeds of the last season," Nicol observes, "be sown without taking this precaution, or something similar, the plants will not be fruitful; but will run much to vines, and show chiefly male blossoms."

3286. Sowing. Abercrombie says, "Having moulded the bed, and proved the heat, sow in pans three inches, or pots four inches, deep, rather than in the earth of the bed. Sow a second portion in five or seven days, to provide against failure. Do not at once plunge the pots to the rims." (Pr. G. p. 108.)

3287. Treatment till removed to the fructifying-pot. "As soon as the plants appear, give air cautiously; guarding the aperture with matting at night, and on frosty or gloomy days. At favorable opportunities, wipe the condensed steam from the glasses. When the seed-leaves are about half an inch broad, prick the plants into small pots five inches in diameter, three in each pot, giving a little aired water just to the roots; then plunge the pots into the earth of the hot-bed partially, or to the rims, according to the heat. Admit fresh air, every day in moderate weather, at the upper end of the lights, raised an inch or two, according to the temperature of the external air; more freely when sunny than cloudy; shutting closer, or quite close, as the afternoon advances towards evening, or sooner, if the weather changes cuttingly cold; and cover the glasses every night with mats, and uncover in the morning, as soon as the sun is high enough to reach the frames. Give occasionally a very light watering, when the earth appears dry. As the plants advance into the first rough leaves, the first runner-bud in the centre should be stopped, by cutting or pinching the top off, close to the first or second joint; an operation which strengthens the plants, and promotes the lateral issue of fruitful runners. Be careful to support a regular tenor of heat in the bed, by laying, first, an outward casing of straw-litter round the sides, to defend it from the weather; afterwards, if the heat declines, remove the above casing; and apply a moderate lining of hot dung to one or more of the sides. In matting at night, be careful not to drive the rank stem of the linings into the beds, by letting the ends of the mats hang down."

3288. Fructifying-bed. Form it as directed for the cucumber-bed, but six inches deeper; M'Phail says, "four feet high, and after it has stood about a week, tread it down and make it level, and set the frames upon it."

3289. Moulding the bed. Abercrombie directs to "mould it by degrees to eight, ten, or twelve inches' depth; first laying the compost in little hills of that thickness, one under each light, with the intervals earthed only two or three inches, for the present, till the general heat is moderated." M'Phail lays in under each light a small hill of earth about one foot high.

3290. Planting. When the earth of the hills is warmed by the heat of the bed, and the plants have leaves two or three inches broad, or have begun to push lateral runners,
turn them out of the pots, "with the ball of earth entire: set a ball containing one plant, in the middle of each insert, clear over the ball; or set at most two plants under the centre of a large light. After planting, give a gentle watering over the hills and round the roots, avoiding to wet the shanks of the plants: shut down the glasses close, till the heat and steam arise; then give air moderately. Extend a slight shade over the glasses in the middle part of warm summer days, if the plants shrink or flag their leaves, before fully rooted in the hills; which they will be in two, three, or four days after planting."

3291. Temperature. The melon requires a minimum heat of about 65° from the time of germination till that of fructification, and a heat of about 75° to fruit in. (Abercrombic.)

3292. M'Phail, as appears from the tables in his Gardner's Remembrancer, kept his melon and cucumber frames at the same temperature; stating, that if any person keep melons or cucumbers-plants in the same degrees of heat, they will not fail of success. (3245.)

3293. Nicoll's medium heat for melons is 70°.

3294. Heat from three to five pints. The proper temperature must be kept up by repeated linings, at least till the middle of July. After that, sun-heat may suffice to ripen the crop. Till this season, the greatest care must be taken not to burn or over-heat the plants. M'Phail says, "Examine daily with your hand the heat of the bed, pushing your fingers into the dung immediately under the hills of earth in which the plants grow; and if you find the heat likely to be too powerful, pour cold water all round the bottom of the hills of earth, to lower the heat of the bed. Remember this must be daily attended to till the heat of the bed be so declined in the middle, that the roots of the plants be in no danger of being hurt by the heat of the dung under them. In case this necessary precaution has been neglected till the heat immediately of the plants has become too hot, pour plenty of water, 50° warm, round about on the sides of the hills in which the plants grow, and among the stems of the plants, which will bring the earth and dung immediately under the plants to the same degree of heat as the water which is at 50°, and keep the surface of the bed hot and cool, that there is no danger of it being too great for the roots of the plants, watering that part of the bed to keep the burning heat down, of course, must cease, and as the roots of the plants extend, earth may be added to the hills. As soon as the heat of the bed declines, linings must be applied to it, which will set it into a fresh fermentation, and then the surface upon the bed must be examined occasionally, by pushing the hand into it in different parts, and when a burning heat is felt, pour in some water as before directed. In this way you should persevere, still keeping a strong heat in the linings. Remember that the surface of the bed all round about the hills should be left uncovered with earth, and the dung should be loosened occasionally, to let the heat rise freely to nourish the plants. Melons will do without heat in the linings in July; but I found by experience, that they do better by keeping a heat in the linings all the summer. If a heat be kept continually on the linings, and the plants watered sufficiently, they will continue to produce fruit till the middle of October."

3295. Air. As long as weak steam is perceived to rise from the bed, leave an aperture, even at night, for it to escape; guarding against the influx of cold air by a curtain of matting. Admit fresh air to the plants by tilting the glasses more or less at the most favorable hours in a mild dry day. After the bed has come to a sweet heat, shut down close at night. As the fruit enlarges, it becomes more necessary to seize every proper opportunity of admitting air; raising the lights from one to four inches, according to the season, the heat of the bed, and temperature of the external air; shutting close, if that should turn cold, and always timely towards evening. As confirmed summer approaches, admit air still more freely.

3296. Nicol says, "Air should be freely admitted, though not in such quantity as for the cucumbers, which do not require so high a temperature as melons do. In sunshine, however, the mercury in the thermometer should be kept down, by the admission of air, to about 80° or 75°."

3297. M'Phail says, "Look into your melons in the morning, and if there is a dew on them standing like the drops of a wet, or little dew on the edges of the young leaves, it is a good sign; but if there is no dew on them, in the form I have described, they are not in a very prosperous condition. The air in the frames is not sweet: they either want water, or sprinklings of water, or else the heat of the air in the frames is too great in the night. In hot weather, melons are better to have air left at them all night, and in very warm weather to take the glasses entirely off in the evening, and put them on again in the morning: by this means the plants will get a refreshment from the dew in the night."

3298. Water. After the plants are placed on the hills, give opportunely gentle waterings, increasing them as the season and the growth of the plants advance. "Water circumspectly and scantily while the fruit is setting or young in growth, as too much moisture would make it decay. Take a warm morning for watering, before the middle of May; in summer, the afternoon, or evening. Use soft water warmed to the air of the frame; and let as little as possible fall on the setting or new-set young fruit; nor much near the main head of the plants, for fear of rotting that part. Shut down the lights after watering, for a short time; and if in the morning, and a strong sun, spread a mat over, to prevent the sun from injuring the plants by acting on the water lodged on the spray and leaves. As a strong steam will now arise, remove the mats in an hour or two, and raise the glasses at the top, to give vent to the steam and admit air to the plants. As the fruit becomes nearly ripe, lessen the quantity of water given, merely keeping the plant from flagging; and withhold water when the fruit begins to turn color."

3299. Nicol says, water once in four or five days in the afternoon, watering over the foliage. Repeat them oftener as the season and the growth of the plants and fruit advance, in order to swell it off the better. (3287.)

3300. M'Phail says, "If the weather is warm and dry, the melons will probably sometimes require water twice a week; if the weather is wet and cloudy, they will not require it so often." (G. Rem.
PRACTICE by and the and the impregnated constantly fertile the dully

3302. Earthing. Perform this operation as directed for the cucumber, after the heat of the dung has become moderate, earthing up by degrees the intervals between the hills, till the depth of the earth becomes equal. 'Eight or ten inches' depth of earth, M'Phail states to be enough for the roots of the plants to run in, provided the bed, or fermenting mass beneath, be made of leaves of trees, or of dung well prepared; for if the bed under the earth be in a good state, the roots will grow into it, and draw from thence considerable nourishment to the plants. The roots of the melon do not naturally run deep; they extend horizontally, not far from the surface, especially in forcing-frames, where the moist warm air is more confined than in the open atmosphere. In early forcing, leave unfilled up with earth a space of about seven or eight inches wide against the inside of the frames, immediately adjoining the hot linings. "By this method the heat of the linings does more powerfully warm the air in the frames than if the earth was made level home to the sides of the boards of the frames to which the linings adjoin. But if melons be not planted earlier than the month of May, this precaution need not be attended to, unless the weather prove uncommonly cold, and but little sunshine." (G. Rem. p. 63.)

3303. Training. As the plants advance into the first runners, three or four joints in length, if no fruit be shown, stop them at the third joint, in order that they may produce fruitful laterals; and as the runners extend, train them over the surface of the bed with neat pegs. Many of these runners, as the plant proceeds, will show embryo fruit at the joints; but a great many barren ones are occasionally produced, and hence it becomes necessary to regulate them. Abercrombie says, "Cut out the superfluous, unfruitful, or evidently useless shoots, especially the very weak and the most luxuriant; for the middle-sized are the most fertile."

3304. Nicol says, melons should be kept moderately thin of vines, though not so thin as cucumbers, (the foliage being smaller,) which should never be much lopped at a time, as they are also apt to bleed. All bruised, damp, or decayed leaves should be carefully picked off as they appear, and the plants should be cleaned from weeds, and other rubbish that may be conveyed into the frames by the wind, or otherwise.

3305. M'Phail directs to "cut out of the melon-frames all superfluous or decaying shoots. Stop the shoots at a joint or two before the fruit, and also cut off the ends of the long running shoots immediately before a showing fruit, if there is a leading shoot coming out by the side of it; for you ought never always in pruning melons, that a fruit will not swell well except there be a growing shoot before it; and this shoot, which is called a leader, because it leads or draws the sap from the roots to and past the fruit, should be stopped before a joint that will, if the plant is in good health, sprout out again. Do not let your plants get too full of leaves; and cut off the oldest and worst leaves first. This ought to be done, at least once or twice a-week; by which method they will be nearly always in one medium state of thinness, and the plants and fruit will derive advantages which they would be deprived of were they to be allowed to become overcrowded with leaves, and swollen and crowded with fruit. In fact, the mass of fruit gets out at one time. If melons are of a large kind, no more than one or two fruit should be left on a plant to swell off at one time; if smaller, three or four fruit may be left." (G. Rem. p. 278.)

3306. Knight, in an ingenious and philosophical paper on the culture of the melon, states, that his crop failed, because "the shoot ran over and crowded over the vines to such a degree that the leaves on the extended branches, from their proper position, and these leaves being heavy, broad, slender, and feebly, on long foot-stalks, were never able to regain it. " In consequence a large portion of that foliage which preceded, or was formed at the same period with the blossoms, and which nature intended, and even says, to feed the fruit, because it was capable of taking food before the fruit acquired maturity. " To remedy this defect, the plants were placed at greater distances from each other, viz. one plant of the solonica variety, to each light of six feet long by four feet wide. The earth was covered with tiles, and the branches trained in all directions, and hooked down over with pegs. They were thus secured from being disturbed from their first position; the leaves were held erect, and at an equal distance from the glass, and enabled, if slightly moved from their proper position, to regain it. 1, however, still found that the leaves sustained great injury from the weight of the water falling from the watering-pot, and I therefore ordered the water to be poured from a vessel of a proper construction, upon the brick tiles, between the leaves, without at all touching them; and thus managed, I had the pleasure to see that the foliage remained erect and healthy. The fruit also grew with very extraordinary rapidity and imperfection in a degree short time, which I had never previously seen. As soon as a sufficient quantity of fruit (between the twenty and thirty melons) was produced on each plant is set, I would further recommend the production of foliage to be prevented, by pinching off the lateral shoots as soon as produced, wherever more foliage cannot be exposed to the light. No part of the melon should ever be left on a plant, and the runners should be stopped; for if the fruit is too crowded, or by being too much crowded together: for each leaf, when full grown, however distant from the fruit, and growing on a distinct branch of the plant, still contributes to its support; and hence it arises that when a plant has as great a number of growing fruit upon part of its branches, as it is capable of feeding, the branches of other branches, which grow in an opposite direction, prove abortive." (Hort. Trans. vol. 1.)

In another paper (Hort. Trans. v. 238,) we find this ingenious horticulturist describing his mode of growing melons in large pots, and training the shoots on a trellis, fifteen inches under the glass. A mode evidently less certain of success, and more expensive than the common mode: but it is good to try every thing.

3307. Setting. As the fruit-bearers come into blossom, you may assist the setting of the fruit, by impregnating some of the female blossoms with the male flowers, as described for the cucumber. The melon, however, will also set naturally, and produce fertile seeds, if the time of fructification fall at a season when the glasses can be left almost constantly open. (Aber.) Nicol says, he has proved experimentally, that melons not impregnated will not swell off so fair and handsome as impregnated ones; and, therefore, considers it more necessary to attend to this operation in melons than in cucumbers.
Therefore, let nature be assisted in this work, considering that she is more under restraint here, than if the plants grew in the open air, where the wind, insects, and other casualties, might help."  

(\textit{Kal.} p. 384.)

3308. Care of the fruit. As the fruit increases to the size of a walnut, place a flat tile or slate under each, to protect it from the damp of the earth; the slab thus interposed will also assist the fruit to ripen, by reflecting the rays of the sun. (\textit{Abercrombie.})

3309. \textit{M'Phail} says, "The fruit should lie upon dry tiles, stones, or slates, and no leaves or shoots ought to be suffered to lie upon it. When the fruit is young, it is better to have a gentle shade of leaves; but when it is full swelled, it should be entirely exposed to the sun."

3310. \textit{Nicol} advises placing the fruit on bits of slate or glass some time before it begins to ripen, as the flavor might else be tainted; but by no means slate or moss the whole surface of the bed, lest you encourage the red spider. "Think on the reflection of the sun upon the slates or tiles, in hot weather particularly, and of his additional force in shining through glass! It is more consonant to the nature of the plants that they be trained on the earth. By mossing the surface, the indulgent may find a pretext, as it, no doubt, in some measure, lessens the labor of watering. But it is wrong to do so, in so far as it harvests and encourages the breeding of various insects; and, as the fruit approach to maturity, taints it by unpleasant effluvia."

3311. \textit{Time of maturation}. The interval between the setting of the fruit and perfect maturity is generally from thirty to forty days; but the plants in the same bed, and the vines on the same plant, often show some difference in the time of reaching maturity. (\textit{Abercrombie.})

3312. Cutting the fruit. "Ripe melons are distinguished by their full size; sometimes by turning yellowish, more constantly by imparting an agreeable odor; often by the base of the foot-stalk, close to the fruit, cracking in a little circle. On these indications of maturity, the fruit should be cut, before too mellow or dead ripe, that it may eat with a lively sharp flavor. The morning is the time for cutting."

3313. \textit{Nicol} observes that "melons, if allowed to remain on the plant till they be of a deep yellow color, lose much of their flavor. They should, therefore, be cut as soon as they begin to change to a greenish-yellow, or rather, as soon as they begin to smell ripe. They may lie in the frame for a day or two, if not immediately wanted, where they will acquire sufficient color. But if they are let remain many days in the frame, they will become as insipid as if they had been left too long on the plant."

3314. Saving seed. The ordinary mode is to request the seeds of particularly fine fruits, of approved sorts, to be returned from table. The best way, however, is to pick some best ripe fruit, take out the seed, clean it from the pulp, and let it be well dried and hardened; and then put it up in papers. (\textit{Abercrombie.}) Nicol says, wash it very clean, skimming off the light seeds, as those only that sink in water will grow. (\textit{Kal.} p. 396.) Great care must be taken that the sorts, from which seeds are saved, are genuine and distinct. When different sorts are planted in the same frame, this cannot be the case.

3315. Second crop from the same plants. "When the fruit of the first crop is off, a second crop may be obtained from the stools; which often proves more productive than the first. If the first crop is taken before the middle of June, the second will come in at a very good time. For this purpose, as soon as the fruit is cut, prune the plant. Shorten the vigorous healthy runners at a promising joint, to force out new laterals; cutting about two inches above the joint. At the same time take off all decayed or sickly vines, and all dead leaves. Stir the surface of the mould; and renew it partially, by three inches depth of fresh compost. Water the plant copiously; shutting down the glasses for the night. Shade in the middle of hot days; and give but little air until the plant has made new radicles and shoots. Afterwards repeat the course of culture above described, from the stage when the first runners are sent out till fruit is cut."

3316. Nicol says, "When all the fruit of this crop are cut, suppose in three or four weeks, the plants may be pruned for the production of a second crop, equal, and perhaps superior to the first. They should be cut pretty much in, in order to cause them to push plenty of new vines, which will be very fruitful; observing to cut always at a joint of some promise, and to thin out all decayed or unhealthy vines, dead leaves, and runners. Observe, also, to cut at an inch or two above the joint you expect to push, and then to bruise the end of the stem so lopped with the thumb and finger; which will, in a great measure, prevent it from bleeding. The plants should be shaded from the mid-day sun, for a week or ten days; exposing them to his rays three degrees. Now, also, let the mould in the frame be well watered, in order to put the roots in a state of active vegetation; point over the surface, with a small stick, or little wedge; and cover the whole with about two inches of fresh mould. This will greatly encourage the plants, and cause them to make new fibres near the surface. At this period air need not be admitted very freely, especially while the glasses are covered; but, rather, as it were, endeavor to force the plants into new life. After they begin to shoot, water, admit air, prune, train, and otherwise manage the plants as before directed. If the season be fine they may yield you a third crop, by a repetition of the above rules, coming in in September, which might be very gratifying. I once had fifty-two full-sized fruit produced in a three-light frame, a space of ten or twelve weeks, and two dozen a third crop. Of the first crop (twenty-six fruit) two were cut the 10th of May. Thus, a three-light box produced, in one season, 102 full-matured melons."

3317. \textit{M'Phail} says, "If you intend to have melons as long as there is a sufficiency of sun to ripen them tolerably well, you had best put linings of warm dung to some of your beds. These, if applied in time and kept on, will cast a fresh heat into the beds, and with other necessary assistance, the plants will grow as long as you want them."

3318. Late crop on old hot-beds. To ripen melons, not earlier than the month of August, \textit{M'Phail} "generally made beds of dung which had first been used for linings to the early cucumber and melon beds. For this purpose, this kind of dung is better than
new dung, because it does not heat violently, and for a considerable time keeps its heat. Leaves of trees make very good melon-beds, but they do not produce heat enough alone for linings; but of whatever materials melon-beds be made, the air in the frames among the plants should be kept sweet and strong, otherwise the plants will not grow freely. It may be known whether the air be sweet or whether it be not, by putting the head in under the lights, and smelling it. But it frequently happens to be difficult to bring dung-beds into a requisite state of kindliness for these delicate plants, for if the dung by any means get and retain too much water before its noxious vapors pass off by evaporation, it will stagnate and become sour, and, until these pernicious qualities be removed, which requires time and patience, the plants will not grow kindly; and besides this, although corrupted stinking air hinders the growth of plants of the melon kind, it greatly promotes the health and forwards the breeding of different kinds of insects, which feed upon and otherways hurt fruits, and plants, and esculent vegetables of various kinds.”

3319. *Culture of melons in a dung-pit.* “A glazed pit to receive either stable-dung, leaves, or tanners’ bark, is calculated to ripen superior fine fruit. The well of the pit may be formed either by a nine-inch wall, or by strong planking; a yard in depth, from six to eight feet wide, and in length from ten to twenty feet, or more, as required. A low glass case is to be fitted to it, adapted to the growth of the melon. Having raised the plants in a small seed-bed as for the frame crop, ridge them out into the pit in the usual manner. Give the proper subsequent culture; and when the strength of the fermenting mass begins to decline, add linings outside the pit, if enclosed by boards; but if enclosed by a nine-inch wall, cut away as much of the dung and earth within, and throw it out, as will admit a lining of well tempered dung.” (Abercrombie.)

3320. *Culture of melons in a fixed pit.* One such as that proper for the nursing-pinery is here understood; and the plants being raised in the usual way, and the bed, whether filled with dung, tan, or leaves, or a mixture of these, being moulded, plant about the end of July. Nicol prefers for such late crops “the early golden cantaleupe, the orange cantaleupe, and the netted cantaleupe, planting a part of the pit with each. A very mild bottom heat is sufficient for the purpose here in view; and if the pit have been occupied in the forcing of asparagus, French beans, or strawberries, on a bark, or bark and dung, or on a bark and leaf heat, it will require no other preparation than to be stirred up, and have a little fresh materials added; keeping the fresh bark, dung, or leaves well down, and finishing the bed with some of the smallest and best reduced. When it has settled a few days, let it be moulded all over to the thickness of twelve or fifteen inches; previously laying on a little more of the above small materials, in order to keep the plants well up to the glass, as the bed will fall considerably in the settling. It should be formed, and the mould should be laid on, in a sloping manner, from back to front, so as in some measure to correspond with the glasses. All being ready for the plants, they may either be planted in a row in the middle of the pit, at two feet apart, or may be planted in two rows at four feet apart; or, if they have been planted, in nursing, three in a pot, plant in the centre of each light, as directed for the common hot-bed in March. Let them have a little water, and be shaded from the sun for a few days; exposing them to his rays by degrees. The future management of the plants differs in nothing from that of melons in a hot-bed, till September, when it will be proper to apply fire-heat. About the beginning of September, it will be proper to apply fire-heat, in order to further the progress of the late fruit, and to dry off damps. Let the fires be made very moderate at first, however, and increase their strength, as the season becomes more cold and wet. Keep the mercury up to about 70° in the night; and in the day, by the admission of air, keep it down to about 80° or 75°. Very little water will now suffice for the plants, as their roots will be fully established, and be spread over the whole bed; the heat of which will also now have subsided. They should only, therefore, have a little water once in eight or ten days; and, as the fruit begin to ripen off, entirely withhold it. Keep the plants moderately thin of vines and foliage; be careful to pick off all damped leaves as they appear; and fully expose the fruit to the sun as it ripens, in the manner directed for melons in the hot-bed. In this manner, I have often had melons in October and November, fully swelled, and in good, but not of course in high perfection, for want of sun to give them flavor. Any who have a pit of this kind, however, for the forcing of early vegetables, strawberries, flowers, &c. cannot, perhaps, occupy it to a better purpose in the latter part of the season; as the trouble is but little, and the expense not worth mentioning.” (Kal.)

3321. *Culture of melons in M’Phail’s brick-bed.* The inventor of this pit says, “For the purpose of raising melons early, for many years I cultivated them on a brick-bed, on the same construction as that which I invented for rearing early cucumbers, excepting only that through the pit of each three-light box I carried no cross fluxes. In each three-light division I made the pit about three feet six inches wide, and ten feet long, and three feet deep below the surface of the fluxes. When this bed was first set to work, I had the pits filled level with the surface of the fluxes with well fermented dung, or with the dung of old linings from the cucumber-beds. On the surface of the dung in the pits, I had
laid about ten inches thick of good earth, in a ridge of about twenty inches wide, from one end of the pit to the other. When this was done, I made a lining round the bed, and as soon as the earth became warm, I set the plants into the ridge of earth, and gave them a little water, and kept a strong heat in the frames, and filled up the pit gradually as the roots and plants extended themselves. The dung or leaves of trees in the pit require not to be changed every year, neither need the earth for the plants be removed entirely every season, for by experience I found it to do very well by digging and mixing with it some fresh earth and manure in winter, and exposing it to the rains, the frost, and the snow. In forcing melons early, the surface of the cross flues, as well as of the surrounding or outside ones, should be kept bare of mould till the days in spring get long, which will let the heat of the linings arise freely through the covers of the flues to warm the air among the plants. After the cross flues are covered with earth, those which surround each frame may be left uncovered till the month of May or June."

(G. Rem. p. 64.) The culture in the brick-bed is in other respects the same as that already given for *melons in frames*, and *cucumbers in brick-beds*. (3298.)

3392. Culture under hand-glasses. A succession, or late crop, to fruit in August and September, may be raised on hot-bed ridges under hand-glasses.

3323. Sow in a hot-bed, from the middle of March to the middle of April. When the plants have been up a few days, while in the seed leaves, prick some into small pots, two plants in each; water, and plunge them into the brick-bed, taking care that the young plants are not injured or bruised. Some are ready from two to four inches long, and ready to shoot into runners. From the middle of March to the third week of May, when the plants are a month or five weeks old, they will be fit to ridge out under hand-glasses.

3324. Forming the bed. With well prepared stable-dung, or, with a mixture of fermented tree-leaves, build the hot-bed four feet wide, and two feet and a half thick, the length according to the number of glasses intended, allotting the space of four feet to each. In a week or ten days, or when the dung and leaves, is brought to a sweet well tempered heat, mould the bed ten or twelve inches thick; this is done, and the bed was cleaned, by turning out the plants, shut close at night. Give a little water, and place the glasses over close.

3325. Routine culture. From about nine in the morning till three in the afternoon, of the first two or three days, shade the plants till they have taken root; when admit the sun more freely; yet only by degrees from day to day, till they can bear it fully without flagging much. Give air daily, in temperate weather, by pulling back the south side of the bed for the two: the other two, keep the glasses over the plants, shut close at night. Cover with mats till morning; constantly keeping the glasses over. Give occasional moderate waterings, with aired water. Cover in the day-time with mats, in bad weather, or heavy or cold rains; and continue the night-covering till confirmed summer in July. Meanwhile, attend to the heat of the bed: if this be declined, so that the minimum temperature be not 58°F at night, with the aid of matting, line the sides with hot dung, covered with a layer of mould. The revived heat from the lining will forward the plants in fruiting; while the earth at top, will enlarge the surface for the runners, and be the bed for the roots. When the runners have extended considerably, and filled the glasses, they must be trained out. Accordingly, at the beginning of June, in favorable settled warm weather, train out the runners; cutting away dwindling and useless crowding shoots: then the glasses must be raised all round, two or three inches, upon props, to remain day and night. Cover with mats in cold nights and bad weather, by pulling back the south side of the bed, or inserting the glasses over the glassed bedding, or sloping waterings, as necessary, in the morning or afternoon. Oiled-paper frames, formed either archwise, or with two sloping sides, about two feet or two and a half high, and of the width of the bed, are very serviceable in this stage. Some persons use them from the first, under a deficiency of hand-glasses. But the proper time for recourse to them is when the plants have been forwarded in hand-glasses, till the runners require training out beyond the limits of the glasses, some time in June: then removing the glasses, substitute the oiled frames. As these paper screens will entirely cover the bed and plants, over which they are to remain the rest of the season, they will afford protection from heavy rains or tempests, as well as from moderate weather, and be the means of checking from the excessive heat of the sun, while, being bellied, they admit its influence of light and warmth effectually. Give proper admission of free air below, and occasional watering. With respect, however, to the crop, for which no oiled-paper frames have been provided, continue the hand-glasses constantly on the bed, over the main head and stem of the plants, throughout the season, to defend those capital parts from casual injuries by the weather. Throughout June, and thence to the decline of summer, be careful, if much rain, or other unfavorable weather, or cold nights occur, to shelter the beds occasionally with an awning of mats or canvas; particularly when the plants are in blossom. Likewise, turn in some of the best full-set exterior fruit, under the glasses; or some spare glasses might be put over the outside melons, to forward them without check to maturity.

3327. Crop. Some will be ready to cut in July, others in August the more general time, and in September; they being generally, after setting, from thirty to forty days in ripening. The crop coming in at the same time as melons, are not ridged off from the bed, but are protected by skylights; and the fruiting in the bed of melons by glassed frames, or supports of slates laid upon the mould, and not overlapping. There is another row of posts (d, d) two feet six inches high, to which boards are nailed on

---

**Book I. CULTURE OF THE MELON.**

---
the north face, forming a space (e, e) three feet wide, extending the whole length of
the bed on its north side, and this is filled with mowings of grass, weeds, fallen leaves,
haulm, and other refuse of the garden. The melon-plants (f) grow on the inclined plane,
beneath which is old spent tanners' bark trodden hard (g), and over it nine inches of me-
lon soil. The plants are placed on this bed in May, under hand-glasses; the shoots, as
they advance, are pegged down. The fruit is cut in August, and from that time till the plants are killed by frost in October.

(Hort. Trans. v. 346.)

3330. Insects and diseases. To prevent melon-plants from being infested with insects,
or injured by disease of any kind, no better method can be adopted than to keep the
plants constantly in a healthy, vigorous, growing state; for this purpose, M'Phail ob-
serves, "they must be constantly attended to, giving them plenty of heat and water. In
warm weather, in the spring and in summer, they should be watered occasionally all
over their fruit and leaves, till the earth in which they grow be thoroughly moistened,
and a stronger heat than usual kept in the frames about the plants for a few hours; also
the lights should be shut down every afternoon, with a good strong heat among the
plants. If there be sufficient moisture in the earth, the greatest sun-heat in the afternoon
will not hurt the plants, but it might scorched the sides of large fruit exposed to the sun-
beams operating upon the glass, which should be guarded against. The frames and
lights should be kept clean, and painted over once every other year.

3331. Mildew and canker. "Melon-plants are subject to be infected and hurt by the mildew and by
the canker. These diseases come upon them because they are not in a good climate, they have not a
sufficiency of heat, or the dung and earth of the bed is in a stagnated state. Melon-plants are liable
to be greatly injured by the red spider, which increases surprisingly in hot dry weather. As I said before, the
practitioners of hot-bed art will prevent plants from the inroads of disease and insects but heat, sweet air, and a
sufficiency of water, which sweetens the atmosphere, and makes it healthy for vegetables as well as for animals. And nothing will eradicate disease and insects from melon-plants but good management, strong
heat, and plenty of water given all over them. Diseased plants, or plants much infested with insects, cannot
prosper good healthy fruit. The mildew is a most pernicious disease to all sorts of plants. On melons it
generally makes its first appearance on the oldest leaves, and on the extremities of the young shoots.
The cause of it, I apprehend, is unhealthy nourishment comprehended in the elements, or their not har-
monising in the promotion of the growth of the plant; for by practitioners it may be observed, that
when a dung hot-bed gets into a stagnated sour state, the plants do not grow kindly, the air in the frames
is saturated with unhealthy particles, and so also must be the juices drawn into the plants by their roots.
These must breed diseases, if preventive means be not applied. It cannot be reasonably supposed that
plants of a delicate nature will continue in a healthy state, growing upon a heap of stinking dung, and in
confined air."

3332. Red spider. "When melon-plants have become diseased, or much infested with the red spider,
they should either be destroyed or effectual means used to cure them. To destroy the plants is easy; to cure
them by preventively curing means, as are put in practice: get plenty of horse-dung thrown up in a large
heap, turn it over once or twice, shaking and mixing it well, and let it lie till its rankness be somewhat
evaporated, and if there be linings at the beds, take them entirely away; examine the dung of the beds,
and if it be wet and has a bad smell, take a sharp-pointed stake, and make holes all round in the sides
of the beds into their centre, in such a slanting way that the water may easily run out of them; then
make a strong lining of the prepared dung all round the beds, and by occasional augmentations keep up
the linings nearly to a level with the surface of the earth in which the plants grow. As soon as the
linings have cast a strong heat into the beds, scatter some flour of sulphur all over the plants, and keep as
strong a heat in the frame as the plants can bear; a heat of 120 degrees will not destroy them, if the steam
of the linings be prevented from getting in among the plants. Water the plants all over their leaves about once a week with clean water 100 degrees warm, and if the sun shine, keep the lights close shut down all
day, and cover them over at night, leaving a little air all night at each light, to prevent a stagnation of
air among the plants. Continue this process till the mildew and the insects disappear, and the plants
appear to grow freely, and afterwards manage them in the usual way, taking care to keep up a good
strong heat in the linings. This method sets the old stagnated bed in a fermentation, which makes the
moisture run out of it, and dries it so, that water given to the plants has free liberty to pass off. If
the linings do not heat the air in the frames sufficiently, let some of the earth in the inside all round the sides
of the boards be removed, to let the heat from the linings rise freely in the frame."

Sect. VIII. Forcing the Strawberry in Hot-houses, Pits, and Hot-beds.

3333. The strawberry is forced in every description of forcing-house, and also in the
pinery, though the heat of the latter often prevents the setting of the blossoms. Where
they are forced in large quantities, it is a good method to apply a pit to their sole culti-
vation. M'Phail says, "They will occasionally do well in a hot-house for growing the
pine; but a heat sufficient to force peaches and nectarines is more natural, and likely to
secure the obtaining of good crops of fine fruit. A good way of forcing the strawberry," he
adds, "is to bring them forward in a gentle heat in melon-frames, till the fruit be
nearly about half-swelled, and then to give them a stronger heat to ripen them." (Gr.
Rem. 29.) Nicol thinks "the climate of the cherry-house most suitable to the nature
of strawberries; they will do well in a hot-bed; but the best method is to force them in fluid pits, such as that for nursing pines."

3334. Soil. All agree that strawberries to be forced in pots require a strong and a very rich loamy earth.

3335. Choice of sorts. Abercrombie and Nicol recommend the alpine and scarlet Virginia; to which Nicol adds the wood strawberry. Morgan (Hort. Trans. vol. ii. p. 376.) begins with the alpines; next he takes the Bath scarlets and common scarlets; and after these the pines.

3336. Potting and preparation of the plants. Abercrombie says, the plants selected should be two years old, having attained a full bearing state. It conduces to the perfection of the fruit, to put as many plants as are intended to be forced into pots, that they may be previously nursed for a longer or shorter time, according to the age of the stool.

3337. New runners of the present summer may be potted in July and August and nursed in pots for two seasons, having the blossoms pinched off in the second. This course of preparation is attended with most trouble: but the crop repays it. Three offsets may be planted in one large pot.

3338. Runners made last year may be potted in April and then plunged in the earth, to be nursed throughout the growing season with a view to forcing, having such blossoms as appear pinched off, while the roots are carefully watered.

3339. Stools of two years' standing, which have borne one crop, may be put into pots in August, September, nearly sufficient to fill a nine or ten inch pot, of plants three or more years old. Others plant runners of the former year in April, three or four in a large pot, or two in a middle-sized one, and plunge them in the earth all summer, giving them occasional waterings, and taking proper care of them. These succeed better than old roots, treated as above. But when I was in the practice of forcing strawberries, I used to prepare my forcing houses in May, or early in June; in July or August, I planted runners of that season, three in a nine or ten inch pot, watered them, and placed them in the shade for a few days; then plunged them to the brim, in a freely exposed situation. In October, their leaves were dressed off, and the plants trimmed to perfection, they were left with a little soil, in order to give the pots the effects of frost. The following spring, any flowers that made their appearance were pinched off; and throughout the summer, the plants were occasionally refreshed with water, and kept clear from weeds. In autumn, the leaves were again dress'd off as before; and when taken up for forcing, the pots were dressed, and fresh earthed at top, previous to being planted in the forcing-house. This method of preparing the plants is no doubt more troublesome than either of the above-mentioned; but the plants, by being completely established, and of a proper age, produce better crops. I have tried all the three ways repeatedly, and prefer the last.

3340. M'Phail says, "Strawberry-plants intended for forcing should be planted in pots eight or ten months before they are ready for the forcing-house; or, strong plants may be taken up with balls of earth about their roots, and be potted and set into the forcing-house immediately."

3341. Nicol says, "Some force old roots or stools, and others the runners only. Those who force the old roots generally lift and pot them about October or November; lifting a bulk from the bed or row, nearly sufficient to fill a nine or ten inch pot, of plants three or more years old. Others plant runners of the former year in April, three or four in a large pot, or two in a middle-sized one, and plunge them in the earth all summer, giving them occasional waterings, and taking proper care of them. These succeed better than old roots, treated as above. But when I was in the practice of forcing strawberries, I used to prepare my forcing houses in May, or early in June; in July or August, I planted runners of that season, three in a nine or ten inch pot, watered them, and placed them in the shade for a few days; then plunged them to the brim, in a freely exposed situation. In October, their leaves were dressed off, and the plants trimmed to perfection, they were left with a little soil, in order to give the pots the effects of frost. The following spring, any flowers that made their appearance were pinched off; and throughout the summer, the plants were occasionally refreshed with water, and kept clear from weeds. In autumn, the leaves were again dress'd off as before; and when taken up for forcing, the pots were dressed, and fresh earthed at top, previous to being planted in the forcing-house. This method of preparing the plants is no doubt more troublesome than either of the above-mentioned; but the plants, by being completely established, and of a proper age, produce better crops. I have tried all the three ways repeatedly, and prefer the last."

3342. He raises his alpines from seed, sowing in January in frames or boxes, to be placed in a gentle heat; he hardens them after they come up by removal to a cooler situation; pots in May in pots six inches diameter and six inches deep. In October they are in flower, when he puts them under shelter, and in the latter end of November he plants them in the forcing-house or potting-house, well watered through the winter. The sets, lets, and the plants in a pot, of the same size as those used for the alpines in May, or early in June, taking the runners of the previous year; he picks off the blossoms as they appear, and keeps them in a shady place till January, when he places them in the forcing-house on shelves eighteen inches from the floor; those in glass, each pot in a pan. The pine-strawberries he pots in the same manner, and takes them into the forcing-house in February or March.

3343. Time of beginning to force. If the fruit be wanted very early, the plants are put in hot-beds, or pits, in October; but the crops from strawberries so forced, Nicol thinks hardly worth the trouble. Abercrombie says, "Begin to force strawberries about nine weeks before you want to gather fruit. Plants excited before the first of January seldom repay the trouble; and in proportion as the time of beginning to force approaches the vernal equinox, the returns are more abundant. To have a succession, reserve sets of potted plants for removal into a house, or frame, every three weeks, till the middle of March." He adds, "Strawberries taken into the house in March, fruit in higher perfection than those forced earlier."

3344. M'Phail and Nicol begin in January. The latter observes, "Those who force strawberries to a considerable extent, perhaps a thousand pots, bring them in, in different successions, perhaps a hundred or two a week, for several weeks. Nicol recommends (Hort. Trans. vol. ii. p. 376.)" when the weather begins to get cold in September, strawberries of the alpine kind in pots may be set in a forcing-house or brick cell; and if they be in good health, they will produce fruit for a considerable time. They require only a gentle heat of from 50 to 60 degrees; give them water occasionally, but as there is no constant blossom and fruit on them, they need not be watered all over broadcast. Give them great plenty of air: they only require protection from heavy rains and cold weather."

3345. MORGAN, as we have noticed above (352), begins to force alpines in November, the scarlets in January, and the pines in February and March. Thus ensuring, as he says, a successional supply of fruit from October till June.

3346. Temperature. Abercrombie says, begin at 40°, and raise the heat as in the cherry-house. When a pit is employed, Nicol directs the pots to be plunged in a mild bark-heat; and the temperature, by the aid of the flues, to be kept at 50°, and 55° or 60° in sunshine. Such treatment will make the plants thrive, and the fruit set freely. M'Phail begins with the heat of a frame on dung, or a pit, and the
moves to the peach-house; and, after the fruit is set, removes his plants to ripen in the vineyard or stove. Scarets, he finds, bear more heat than the other sorts.

3347. Air and water. The former is to be freely admitted in good weather; and the latter plentifully supplied at all times, until the fruit begins to ripen off. Then it is to be withheld, lest the flavor become insipid. Morgan prefers supplying it from pans, in order not to rot the hearts of the plants. He gives as little water as possible when the plants are nearly ripe, this being essential in order to have good-flavored fruit.

3348. Treatment after gathering the fruit. The strawberry, it is generally considered, will not force the year after like fruit-trees; but must be rested by plunging in the open ground for one or two years, pinching off all blossoms as they appear. Williams states, that "the scarlet strawberry, after affording a crop of fruit in the hot-house early in the spring, if carefully removed out of the pots or boxes, and placed in the open ground, will yield another crop of fruit in September. The second crop is very abundant, the warm rains of July and August proving highly favorable to the growth of the fruit; and, as there is no other strawberry to be had at this season of the year, except the alpine, the addition of the scarlet makes a pleasing variety in the dessert." (Hort. Tr. vol. ii. p. 93.) Morgan observes, without limiting his observation to any one sort, that "after the fruit has been gathered from the plants, the pots should be plunged into a shady border, giving them a good watering, and at the same time cutting off the leaves: when thus treated, they will, in the year following, produce as good crops in forcing as fresh-potted plants; if not wanted for this purpose, they may be turned out into the natural ground, and will then bear a crop in the autumn of the same year, as described by Williams above."

**Sect. IX. Forcing Asparagus in Pits and Hot-beds.**

3349. Asparagus is forced with equal, or with greater success, and with less trouble in filled pits than in dung hot-beds. M'Phail recommends his brick-bed for this purpose. The roots, Nicol states, may either be forced on bark, or on dung, or on dung and bark. But old half-rotten bark, in which there is not much heat, is to be preferred. Next to this he uses well fermented dung underneath, and old bark to the thickness of a foot or fifteen inches at top. "If dung alone, or a mixture of dung and leaves be used, it should be carefully fermented, and should be in a state past heating violently before it is put into the pit. In this case, observe to finish the bed with the smallest and driest part of the materials." Ross (Hort. Trans. vol. ii. p. 361.), instead of a warm stratum of dung or tan, places his roots on a cold bed of the latter, on which nursing-pines or melons have been grown, but which has ceased to ferment. He then applies warm linings to the sides, and thus produces the requisite degree of heat. Sabine, having seen in Ross's pits, in January, 1817, some of the strongest asparagus he ever noticed at that season, concludes, "that the weak and drawn state of forced asparagus is occasioned by the action of the dung immediately on its root." He therefore greatly prefers Ross's mode.

3350. Choice of plants. M'Phail says, take roots of any age that bear fine grass. Nicol says they should not be under four years old, nor above eight. Abercrombie takes plants of two or three years' standing.

3351. Planting. M'Phail says, "Lay on the surface of the bark-bed from six to eight inches of vegetable mould, or any other sort of light earth that the heat may easily ascend through, and of such a texture as does not retain water. Take up plants, no matter what age they are, which produce fine asparagus, trim their roots, and place them in rows on the beds; when one row is laid, strew a little fine mould among the roots, then proceed in the same way with one row after another, keeping them on a level, as the surface of the bed at first lay, till you have finished planting them; then lay among the buds and roots some fine vegetable, or other light rich mould, working it in among them with your fingers, and cover the buds over about one inch thick, and above that lay three inches in depth of vegetable mould not very rotten, but such as the water will run quickly through. If you have not got vegetable mould of this description, old tan, not very fine, will answer the purpose equally well. If there is a strong heat in the bed, let the glasses remain off till it begin to decline." Nicol directs, that the roots in the beds in the open air, which are to be taken up and forced, should be kept covered with litter, so as to be easy to come at in time of frost.

3352. Time of beginning to force. Abercrombie says, if in mid-winter, begin six weeks before you propose to have a crop; when the days are longer, five weeks, or but a calendar month before. Nicol says, those who wish to have the asparagus on the table at Christmas, should prepare for forcing it in November, to have a continual succession.

3353. Temperature. The temperature at night should never be under 50°. In the day-time keep the maximum heat down to 62°. "If by the heat of the bark or dung, and the use of mats or canvass covers at night, the thermometer stand as high as 50°, fire-heat will be unnecessary; but otherwise recourse must be had to the flues. A very moderate degree of fire-heat, however, will be sufficient; and a small fire made in the
evening will generally answer the purpose. Sometimes, in dull hazy weather, a fire may be necessary in the morning, in order to enable you to admit air more freely, and to dry off damp.” (Abercrombie and Nicol.)

3354. Air must be freely admitted every day in some cases to allow any steam to pass off; and for the sake of the color and flavor of the plants. As the buds begin to appear, as large portions of air must be daily admitted as the weather will permit.

3355. Water. When the asparagus-bed has, after planting, stood two or three days, and when the heat will have begun to warm the root, give the plants a sufficient watering. Pour it out of a pot with a rose on it, to imitate a shower of rain; let the bed have enough to moisten the mould well, and to wash it in among the roots. Repeat such waterings now and then. Nicol says, the roots must have moderate supplies of water: once in three or four days, if the heat be not violent; and if otherwise, oftener.

3356. Gathering. “By the time the buds have come up three inches above the surface, they are fit to gather for use, as they will then be six or seven inches in length. In gathering them, draw aside a little of the mould, slip down the finger and thumb, and twist them off from the crown. This is a better method than to cut them; at least it is less dangerous to the rising buds, which come up in thick succession, and might be wounded by the knife, if cutting were practised.”

3357. Forced roots. The roots, after they have furnished a crop, are considered useless for future culture, because no leaves having been allowed to develop themselves, of course no buds could be formed for the succeeding year.

3358. Successional supplies. If the pit in which asparagus is forced, be twenty-five or thirty feet long, it will be enough, for the supply of an ordinary family, to fill one half at a time. If the second half be planted when the grass in the first half is fit for use, and so on, a constant succession may be kept up in the same pit for any length of time required. In order, however, to forward or protract the growth of the one part or of the other, the pit may be divided in a temporary way, by fitting a board neatly under the middle rafter. By this means, one half may be kept cooler or hotter than the other, by matting or not matting, or by the admission of more or less air, &c. “In filling the first end of the pit a second time, if bark be used, it will not be necessary to add fresh materials; as trenching over the bed will be found to answer the purpose, even a third time. And in using dung, the stirring up of the old, and adding as much new as will raise the bed to a proper height, finishing with the smallest and best fermented part, will generally be sufficient for a second filling. For a third filling, one half new dung may be necessary, which, however, should be moderately fermented, and be kept well down.”

3359. Forcing asparagus in hot-beds. Asparagus may be brought to perfection in hot-beds at any time from November till it comes in the natural ground. When it is intended to have a constant supply from hot-beds, M'Phail recommends one to be made every fortnight, and Abercrombie once a month, from November till April. This must, of course, be arranged according to the size of the hot-beds and number of the family.

3360. Forming the hot-bed. M'Phail says, “Get a quantity of good dung well prepared, by putting it together in a heap to ferment, that the rancidity of it may be evaporated, by turning and mixing it several times when there is a strong heat in it; make it up into a bed about three feet high, and four or five inches larger all round than the size of the frames, which are to be set upon it. When it is made, set the boxes and glasses on, and let it heat and stand till it is sweet, which may be known by the smell of it; then tread it level, and loosen up the surface again, that the heat may have free liberty to arise.” In this stage, Nicol covers the whole with “rolls or squares of turf, cut so as again to join exactly; which lay green side down, and beat them well with the back of the spade, that the whole may be close and compact, in order as much as possible to exclude steam.” To this practice M'Phail objects, as preventing the water from sinking freely into the bed; and if there be a sufficient heat in it for winter forcing, unless it receive water, it must become dry and husky. The method, he says, is an old one practised fifty years ago, and now exploded by every good gardener. Instead of turf, therefore, M'Phail and Abercrombie, after setting on the frame, direct, with the bed from five to eight inches thick, to use any sort of light earth. Nicol says, “I have often used old bark reduced to a fine mould, without any mixture of earth, and have sometimes mixed it with fine sandy earth, with little difference in the success; only I have observed, that when the roots were placed in bark entirely, the buds would come a few days earlier.”

3361. Planting. Proceed as directed for planting on a bark-bed. Abercrombie says, “Provide from five to nine hundred (he elsewhere says six hundred) roots for a hot-bed under a three-light garden-frame. Having prepared the roots, mark out on the surface of the mould the width of the frame; then, beginning at one end, raise a small ridge of earth crosswise, and proceed to planting; placing the first course of roots nearly upright, close against the said ridge, and with the crowns in contact, either upon the sur-
face of the level earth, or with only the lower ends of the roots a little inserted; place more against these in the same manner, as close together as possible, and extending to the width of the frame: add successive ranges, as close as they can be set, with the crowns of an equal height." Where the bed is completely planted, the crowns are to be earthed over regularly. Some, as Abercrombie, cover with two inches of light earth, adding, when the buds appear, three or four inches of additional earthing; others, as Nicol and McPhail, cover at once with four or five inches, adding no more afterwards. The planting completed, the next thing is to put on the lights, which are to be kept close shut down till the heat begin to rise in the frame; which will generally happen the second or third day, when air is to be admitted, in order to pass off the steam, and dry the surface of the mould. Air must be given every good day till the buds begin to appear above ground; and then more freely admitted to give-color and flavor.

3362. Produce in hot-beds. Nicol says, "An ordinary-sized three-light frame, completely filled with roots, and properly managed, will only yield a dish every day for about three weeks."

3363. Successional supplies from hot-beds. On the above estimate, if a constant succession of asparagus be required, it will be necessary to make up a bed every eighteen or twenty days till the middle or end of March. Each successive bed may be made a little lighter; and less trouble will be required as the season advances. (Kal. 347.)

3364. Forcing the roots as they stand in the open ground. Stir the surface of any bed or beds in full bearing in the general plantation; then, having raked it fine as in the usual spring dressing, cover three inches with the siftings of old tan, and on that lay a layer of fermenting dung, as in forcing rhubarb or sea-kale. This mode has been but seldom practised; but we consider it likely to succeed to a certain extent.

3365. Mètrass " finds, that asparagus may be forced in a vineyard, by planting the roots in the border, behind the flue, where no vine roots are." (Calcut. Hort. Mem. iii. 164.)

3366. Sea-kale and rhubarb may be, and sometimes are, forced in the same manner as asparagus; but the most general mode is to excite them where they stand in the open garden, by the application of warm dung, with or without earth in pots, or other covers. (See the Horticultural Catalogue.)

Sect. X. Forcing Kidneybeans.

3367. The kidneybean may be successfully forced in pits, hot-houses or forcing-houses, and hot-beds. The more general mode is to force in the pine-stoves; the same heat which suits the pine-apple, suitting the kidneybean, which is a native of India. Nicol prefers a flued pit, such as that used for nursing pines: and Abercrombie says, "Where there are no hot-houses, or where kidneybeans are to be raised in quantities for the market, the most economical and successful mode will be found a flued pit, prepared as directed for asparagus, but with a stronger bottom heat."

3368. Soil. All agree in recommending light vegetable earth.

3369. Sorts. Abercrombie recommends the early speckled, early negro, and dun-colored dwarfs. Nicol says the speckled dwarf is the best sort.

3370. Sowing. Sow in flat boxes or pans of fine light earth thickly, and cover to the depth of an inch. Let them be placed in a stove or hot-bed, and have moderate supplies of water, and they will be fit to plant when about three inches in height. Plant them in rows across the bed of the pit fifteen inches apart, and three inches distant in the line.

3371. Culture. Water after planting, and afterwards, as required; give abundance of air every fine day, and earth up the plants as they advance in growth in order to give them strength.

3372. Time of beginning to force. McPhail says, "If you wish to endeavor to have kidneybeans green all the year, you should plant the seeds, and begin to force in August." Abercrombie observes, "Some forcers, quite in opposition to the season, raise kidneybeans in August, and thence till the 21st December, which day may be regarded as the boundary between late and early forcing."

3373. Temperature. The heat by fire in the night need not exceed 50°, according to Nicol; but Abercrombie recommends 60° for a minimum, and 75° for a maximum.

3374. Successional supplies are to be obtained by sowing every month or six weeks, for which purpose the pits may be divided by temporary partitions, as recommended under Forcing Asparagus. (Sect. IX.)

3375. Forcing in hot-houses. "The most early fruit in perfection," says Abercrombie, "is obtained by culture in a stove, sowing from midwinter till the end of March." Sow in pots, or oblong boxes, containing a mixture of light fresh earth and vegetable mould, depositing the seeds either in a triangular or quincunx order, and full an inch deep. If the plants are to fruit where sown, the cradles should be ten inches deep; but, if they are to be transplanted, which admits a greater number in the same space, the seed-pots or boxes may be shallow. Do not fill the cradles with mould at first, to allow of
gradually earthing up. When the beans have germinated, sprinkle the earth with water; after the plants have risen, give moderate waterings every other day — the last crops may want water every day. Sprinkle also the leaves with water warmed by standing in the house. Those raised in shallow pans should be transplanted for fruiting when two or three inches high. It is sometimes proper to stop luxuriant runners. These incidental crops may stand in rows, on the flues, or on shelves; but take care they do not shade the pines and other principal plants. For succession, sow every fortnight or three weeks.

3376. Forcing in a peach or cherry house. Nicol observes, "French beans may be successfully planted out in the borders of an early cherry-house or peach-house, so as that they may not be overmuch shaded by the trees; but they seldom do much good in a vinery, where they are shaded by the whole foliage of the vines."

3377. Forcing in a common hot-bed. "Under the deficiency of a house, you may have recourse to a hot-bed and frame; but the culture will be attended with more trouble, the course will be longer, and the fruit is rarely so fine and plentiful; nor without fire-heat can the difficulties of late or very early forcing be so well contended with. From the middle of February to the beginning of April is the most successful period for forcing the kidneybean in a hot-bed. The early white dwarf, from its low growth, is to be sown in preference to the kinds recommended for a stove, unless it be intended to fruit the plants in a deeper frame than ordinary. The early yellow and early black are next, as not growing very high. The temperature for the kidneybean is 60° for the minimum, and 75° for the maximum of the fruiting-bed. In forcing soon in the spring, raise the plants on a smaller bed, earthen over with light rich compost six inches deep. Sow the beans thickly, covering them to the depth of an inch. The second hot-bed should be earthened over to the depth of eight or nine inches. Into this transplant the seedlings as soon as they are two or three inches high; setting them in cross rows twelve or fifteen inches asunder, by four or three inches in a line. Or when the season is so far advanced, that one bed with the help of lineings will bring the plants well into fruit, you may sow at once, at the full distance, in a similar hot-bed, to continue for podding. Cover the glass every night with garden-mats; also partially in severe weather. Admit fresh air moderately every mild day, and give occasional gentle waterings. The plants raised in February will come into bearing in April and May, making moderate returns: a new crop every three weeks will keep up the succession: those sown at the beginning of April will last till the middle or end of June, when they will be succeeded by the early half-sheltered crops in the open garden."

3378. Crop raised under glass to fruit in the open garden. "At the end of March, you may sow a small portion under glass, for transplanting into the open garden in the first or second week of May. It is not so well to sow in patches on the surface of the ground, as in small pots, because the plants can be turned out from the latter with less check to their growth when transplanted. Sow three beans in each pot. When the seedlings are two or three inches high, harden them by degrees to the full air; and plant them on a good open border as soon as May as the season will suit. They will yield fruit about a fortnight sooner than the earliest raised under exposure to the weather."

3379. Crop raised on slight heat. "A crop to fruit early in the open garden may be accelerated with more certainty by plunging the pots containing the seed-beans into a gentle hot-bed; or some sown in shallow pans or boxes may be set on the shelves of a stove. Just at the opening of April will be early enough to begin; as the plants will otherwise get too forward for the weather, to proceed well without a continuance of artificial heat. Having nurled them to the proper stage, plant out under a south fence, either three inches apart, if in a single line, or eighteen inches by three, if in two lines; or it may be better to set the plants in patches of nine or seven, to receive the temporary shelter of a hand-glass, lest the transition from a hot-bed, all at once, to the fluctuating air of spring be too violent." (Abercrombie.)

3380. Insects. Nicol observes, that "the thrips often attacks French beans in the hot-house; and, therefore, the plants should be fumigated with tobacco, which destroys that insect."

Sect. XI. Forcing Potatoes.

3381. The potatoe is forced in a great variety of ways; but, "for a fair crop of tubers, which shall be somewhat dry and flowery, and of the size of hens' eggs; plant sets of the ash-leaved variety in single pots, filled one third part with light earth, in January. Place them in a hot-house or hot-bed, earth them up as they appear, and about the middle or end of February transplant them with their balls entire into a pit prepared as for asparagus. Distance from plant to plant one foot each way. Give water occasionally, and admit as much air as possible at all times. Potatoes so managed will produce a crop the end of March or beginning of April." (Abercrombie.)

3382. Forcing potatoes in hot-beds. Abercrombie says, "A young crop is easily obtained soon in spring, by planting the early dwarf, or the sort called mules, on a slight hot-bed. Put in the sets pretty thickly, at six or eight inches square distance, as the potatoes are not to grow large. If planted successively in January and February, they will produce young crops for use in April and May, to be taken up in small portions as wanted for present eating. During the growth of the plants, open the lights fully in the middle of fine dry days; but mat at night to guard against frost. Water attentively as the mould and weather may require."
life, and run less to straw by that management, than when they are sown where they are to remain. Indeed, it would be very well worth while to transplant the earliest crops in the open ground." (Kal. p. 29.)

3398. Beans may be forced in a similar manner, though this is seldom attempted.

SECT. XIII. Forcing Salads, Pot-herbs, &c.

3399. Salads, pot-herbs, and various other culinary plants, are, or may be forced; but the practice in Britain seldom extends beyond pot-herbs and salads; though some have forwarded cabbages, cauliflowers, turnips, carrots, &c., in this way, as is occasionally done in Russia and the north of Germany.

3400. Cauliflower, lettuce, radish, carrot, and onion, M'Phail observes, may be planted or sown in February, "on gentle hot-beds of dung or leaves, to bring them in before those in the open ground. They should have glass frames set over them in cold, frosty, or rainy nights; which may be taken off in fine days, or a great deal of air given to them." Nicol says, "The early horn carrot may be sown in January on a slight hot-bed, or on a border, close by the parapet in front of a pinery, early grape-house, or peach-house. The seeds should be sown in fine light earth, in either case, and should not be covered more than to the depth of a quarter of an inch. If sown on a hot-bed, the seeds may be defended by a frame and lights, or by hoops and mats, from bad weather, and should be covered always at night. If sown on a border in front of a forcing-house of any kind, they may be covered with hand-glasses. When the plants come up in either situation, they should have plenty of free air, as they do no good if they be drawn; they also should have moderate supplies of water. A thin sprinkling of radish or lettuce may be thrown in along with the carrot."

3401. Pot-herbs, such as mint, marjoram, chervil, &c., are planted or sown in pots or boxes, and placed in any house, pit, or frame, in a state of forcing, near the glass, and where they will receive abundance of air in fine weather. They require little or no farther attention, but occasional watering. They may also be planted in rows in hot-beds or pits.

3402. Small salading, such as cresses, mustard, rape, chicory, &c., to be cropped when young, may be treated as pot-herbs; the three first will thrive at a greater distance from the light, and may be sown as practised by the market-gardeners on the floors or borders of cherry and peach houses.

3403. Radish. Abercrombie says, "To obtain the earliest spring radishes, sow on a hot-bed of dung or leaves some early dwarf short-tops in December, January, or the beginning of February. Having made a hot-bed two feet, or two and a half high, in dung, place on the frame. Earth the bed at top six inches deep; sow on the surface, covering the seed with fine mould, about half an inch thick; and put on the glasses. When the plants have come up, admit air every day, in mild or tolerably good weather, by tilting the upper end of the lights, or sometimes the front, one, two, or three inches, that the radishes may not draw up weak and long-shanked. If they have risen very thick, thin them in young growth, moderately at first, to about one or two inches apart. Be careful to cover the glasses at night with garden-mats or straw-litter. Give gentle waterings about noon on sunny days. If the heat of the bed declines much, apply a moderate lining of warm dung, or stable-litter, to the sides; which, by gently renewing the heat, will forward the radishes for drawing in February and March. Remember, as they advance in growth, to give more copious admissions of air daily; either by tilting the lights in front several inches, or, in fine mild days, by drawing the glasses mostly off; but be careful to draw them on again in proper time. Small turnip-radishes, of the white and red kinds, may be forced in the same manner. For raising early radishes on ground not accommodated with frames, a hot-bed, made in February, may be arched over with hoop-bends, or pliant rods, which should be covered with mats constantly at night, and during the day in very cold weather. In moderate days, turn up the mats at the warmest side; and on a fine mild day, take them wholly off." Any sort of radish seed may be sown occasionally for salad-herbs, to be taken while in the seed-leaves, to mix with cresses and mustard. Sow about once a-week in spring, summer, or any season when radish-salad is required, managing it as other small salad-herbs."

SECT. XIV. Culture of the Mushroom.

3404. The edible mushroom (Agaricus campestris, L.) has long been held in esteem in this country. Its peculiar habits, and the method of propagating it, are so unlike those of any other culinary vegetable, that gardeners, till lately, seem not to have generalised on its culture. For a long period back, it seems never to have been produced in any other way than on ridges of warm dung; no one appearing to advert to the circumstance of its being indigenous, and that it may be grown in the open ground in the warmer months.

3405. The cultivation of mushrooms, Nicol observes, "is a process in gardening, perhaps the most singular and curious of any. In the culture of any other vegetable, we
3406. What spawn is. Spawn is a white fibrous substance, running like broken threads, in such dry reduced dung, or other nidus, as is fitted to nourish it. These threads produce, when planted, tubercles in the manner of potatoes. The true sort has exactly the smell of a mushroom. Spawn, when once procured, may be extended or propagated as spawn, without producing mushrooms. (Neill; Abercrombie.)

3407. Producing spawn. This vegetable may be produced by first making lumps, or what are sometimes called cakes of spawn, and afterwards placing them on a slight dung-hot-bed, where the spawn vegetates into complete mushrooms; in which process of making the spawn (as it is termed) different ingredients are used, but chiefly the dung of horses, as said above. This has so far become a branch of trade, as that mushroom-spawn may be had by most of the nursery and seedsmen about all the great towns in the kingdom.

3408. Originating mushrooms without planting spawn. Nicol says, "I have formerly been in the practice of producing mushrooms, however, most successfully, without using spawn, and by a very simple process: I might rather say, without transplanting spawn in the common way, but by making the bed a whole mass of spawn at once, and never disturbing it till done bearing. Beds that are built in the common way, and spawned, seldom produce long; perhaps only a few weeks or months. I have had them continue to yield large crops the year round, and sometimes for two years. But mushroom-beds, in whatever way made, are subject to many misfortunes; and the spawn is of a nature so delicate, that it is quickly destroyed either by too much wet or drought. By making up a bed in the ordinary way, that is, of stable-dung, moderately fermented, to the thickness of about a yard; spawning it over when the strong heat has subsided, and then covering it with light earth, mushrooms may be obtained sooner than by the process I shall recommend. But if this process be more successful, it has the advantage of being more sure; and the time of reaping may be reckoned upon with equal certainty. The difference of time, from first proceeding to make the beds to gathering mushrooms, will generally be three or four weeks. By the first method, you may reap in six or eight weeks; and by the latter, in ten or twelve."  

3409. Proceed thus: "After having laid a floor, as hinted at above, of ashes, stone-chips, gravel, or brick-bats, so as to keep the bed quite dry, and free from under-damp, lay a course of horse-droppings six inches thick over the whole. These should be new from the stable, and must not be broke; and the drier the better. They may be collected every day, until the whole floor or sole be covered to the above thickness; but they must not be allowed to ferment or heat. In the whole process of making up, the bed should be as much exposed to the air as possible; and it should be carefully defended from wet, if out of doors. When this course is quite dry, and judged to be past a state of fermentation, cover it to the thickness of two inches with light dry earth; if sandy, so much the better. It is immaterial whether it be rich or not; the only use of earth here being for the spawn to run and mass in. Now lay another course of droppings, and earth them over as above, when past a state of fermentation; then a third course, which in like manner earth over. This finishes the bed, which will be a very strong and productive one, if properly managed afterwards. Observe, that in forming the bed it should be a little rounded, in order that the centre may not be more wet or moist than the sides. This may be done in forming the sole or floor at first, and the bed would then be of equal strength in all parts. If it be made up against a wall in a cellar, stable, or shed, it may have a slope of a few inches from the back to the front, less or more.
according to its breadth. I have sometimes been contented with two courses, as above, instead of three; and, often, when materials are scarce, have made them up slighter, thus: three four-inch courses of droppings, with one inch of earth between each, and a two-inch covering at top. Such a bed as this I have had produce for ten or twelve months together; but very much depends on the state of the materials, and on the care taken in making it up; also on the after-management. The droppings of hard-

faced horses only are useful. Those of horses on green food will, of themselves, produce few or no mush-

rooms. This I have proved in more than one instance, much to my disappointment. And I have, moreover, found, that the richer the keep of the horses, the more productive are their droppings. I have made up beds from farm-horses, fed partly on hard, and partly on green food; and from carriage or saddle horses, fed entirely on corn and hay; treated them in the same way in every respect; and have found, not once, but always, those made from the latter most productive. Droppings from corn-fed horses may be procured at the public stables in towns, or at inn in the country, any time in the year; and if the supply be plentiful, a bed of considerable dimensions may be made and finished within five or six weeks. In as many more weeks, if in a stable, or dry cellar, or a fluid shed, it will begin to produce, and after two months, or more, if the situation of the bed be cold, it will sometimes be two or three months of producing mushrooms."

3410. Where indigenous spawn may be collected. September is the month in which the mushroom comes to perfection in the open air; and this is the time to look for it in its native habitats. Downs and upland pastures are the primitive situations, whence the seeds seem to be carried by horses and cattle, to what are called secondary situations. Thus "it is found in strength and purity, in the path of a bark-mill worked by a horse, in any other horse-mill track under shelter, in covered rides for horses, in dry half-rotted dung-heaps, and in hot-beds. It is found in a less degree in various other situations." (Abercrombie.)

3411. M'Phail says, "The best of mushroom-spawn is frequently to be found in dunghills which have lain a long time without turning, and which had been formed of horse-dung, scrapings of the manure shed, and tuft cut up about the sides of the stables. Those dunghills which have dried the dunghill, when rain comes about the latter end of August or in September, mushrooms of a good quality may often be seen beginning to form themselves on the surface, like large peas. When these are ob-

served, it is time to take out the spawn, which is generally in hard dry lumps of dung, the spawn having the appearance of whitish coarse pieces of thread."

3412. To preserve indigenous spawn. "Having found cakes of dung which contain the desired spawn, take them up as entire as possible, with the earth adhering, and lay them carefully in a basket or any other conveyance. These are to be stored till used as below, in a dry covered place; and if they were found in a damp state, should be dried in hollow piles, before they are laid together in a mass. The dry spawn may be preserved three or four years. To preserve alike from perishing, and from running before it is planted, a dry shed furnished with a current of air, is indispensable."

3413. Procuring spawn artificially. Wales thus procures spawn: "For this purpose, the month of March is the fittest time, the cattle not being then upon grass, but chiefly upon dry food of one sort or other. Take two barrow-loads of cow-dung, one load of sheep and one of horse dung; dry them well; then break them quite small, so as they may go easily through a coarse garden-sieve. When well mixed together, lay them up in a round heap, finishing at top in a point. It is to be understood, that the operation is to be conducted in a dry shed. Observe to tread the heap as it is put up, which will greatly save it from heating too much. If a stick were thrust into the heap as a proof, and when taken out, if it feels very slightly warm in the hand, the heat is doing well; for, in the whole mode of raising mushrooms, it should be particularly observed to take great care of the heat, as the mushrooms are impatient of either too much heat or cold: the best adapted, and most productive heat I have ever found, was from 55 to 60 degrees of Fahrenheit, and the nearer the beds are to this heat, the greater will be the success. The heat is to be covered with horse-litter, in a state of fermentation, to the thickness of four inches all over. If the shed be warm when the heat is put up, I would recommend old bass-mats rather than dung, as the least over-

heat would spoil the heap. In this state let it lie for one month; then throw the litter a little aside, thrust the hand into the heart of the heap, and take out a handful. If the spawn has begun to run, you will observe numerous small white fibres or threads through the dung. If not begun to run, let another covering be put on above the old one of the same thickness as the first; and after a month more, you will undoubtedly find the heap to abound with spawn. I have had it running in three weeks, and sometimes it has required ten weeks, much depending on the state of the dung. The spawn thus procured is of the very best quality, far exceeding what is got in fields or in old hot-beds. I write from experience, and have not borrowed this mode of procuring spawn from any one. The spawn in this state is not fit for keeping long; and I shall next give directions how to form spawn-bricks, when as many can be made at one time, as will serve for the season, or even for a number of years if required, provided the spawn be kept dry." (Mem. Caled. Hort. Soc.)

3414. Preserving artificial spawn by forming spawn-bricks. The author last quoted says, "Take of horse-dung without litter, three barrow-loads; two barrow-loads of the mould of rotten tree-leaves; two barrow-loads of cow-dung; one barrow-load of old tan-bark, such as is thrown out of the pine-pit; with one barrow-load of sheep's dung; mix all these well together, till the mixture seem to be one compost, and to be as fine and soft as
common mortar, or as the clay used in grafting, as otherwise it would not come easily out of the mould. Then take a small frame, such as brick-makers use for moulding their bricks,—the size six inches long, four broad, and three deep. A portion of the mixture should then be forced into the mould or frame, and the sides of the mould being a little wetted beforehand, the spawn-brick will easily come out without breaking. After the bricks have stood two hours or so, take a blunt or rounded dibble, and make three holes in the middle of each brick, an inch from each other, and about half through the brick; these holes are for receiving the spawn. I find it is the best way to lay the bricks as they are made upon boards, that they may be carried out of doors in a good day to dry. The bricks should be rendered perfectly dry, as the least damp would spoil the spawn. They will often seem dry on the outside, while they continue wet in the inside. The best way to prove them, is to break a brick, and observe how dry it is in the inside. It is to be observed, that great care must be taken in the turning them up upon the boards, for fear of breaking, they being very apt to go to pieces, till nearly fit for receiving spawn. When fit, they are firm, and quite dry on the outside: this happens in the course of three weeks, if the weather be dry and the bricks be rightly attended to.

Now, take fresh horse-litter, which has been laid up in a heap to sweeten as when for hot-beds; lay a bottom course of this six inches thick, whereon to lay the bricks. The horse-litter which is to be prepared for covering the spawn-bricks ought to be rank, because the drier and sweeter the heat, the spawn will work the freer; and, as I stated before, if the weather be warm, the less covering will serve; also, if there be any heat in the old covering at the expiration of three weeks, add no more new covering, as the old will perfectly serve the end. Every hole in the bricks must next be filled quite close up with the spawn; and as the bricks are laid one upon another, the upper side of the brick when laid, must also be covered with spawn: at the same time observing, as the bricks are laid, to keep them as open between one another as possible, so as to let the heat and steam of the dung go through all parts of the heap. The heap is to be terminated at top by a single brick. When all are thus laid, place round the sides and top six inches of the hot dung, which will soon raise a fine moderate heat; observing, that all this must be done in a shed, or where rain cannot enter to cool the dung. After two weeks, add three inches thick of additional fresh dung upon the old; this will renew the heat, and make it work forcibly for the space of two weeks more, when the litter may be taken off, and cleared all out from the spawn-bricks. Before the cover is taken off, it will be proper to lay a little of it aside, and take out a few of the bricks, to see whether the spawn has run all through each brick or not; if not, replace the bricks again, and the cover, and let them remain for ten days longer, when they will be found to be every one, as it were, a solid mass of spawn. They may be allowed to stand and dry for a few days in the heap: they are then to be laid up in some dry place till wanted for use, where they will keep good for many years."

3415. Propagation of mushroom-spawn. M'Phail offers two modes, as follows: "About the beginning of the month of May collect a heap of nearly equal quantities of cow, horse, and sheep dung; add to it some rotten fern-leaves, or rotten dry dung, somewhat resembling spawn, from the linings of hot-beds; mix the whole well together, in the way a bricklayer's laborer makes mortar; spread it on a floor in a cool dry shed, where it cannot dry too hastily, making it about five or six inches thick; beat or tread it firm; and as soon as it is in a fit condition, cut it with a sharp spade into pieces in the form of bricks; set the pieces to dry till they can be conveniently handled; then with a knife make a hole in the middle of each, and put a little piece of good mushroom-spawn into each hole, closing it up with a bit of that which was taken out; then pile the impregnated pieces up in a heap in a hollow manner, so that the air may pass through the heap freely among the pieces, to dry them gradually; and if the shed be light, cover the heap with mats, or any other light covering to keep it dark. When the spawn has extended itself through every part of the prepared pieces of the mixture, lay them out separately, that they may be perfectly dried, which will prevent mushrooms from growing out of them; which, if suffered, would exhaust the spawn so, that it would be much weakened. In a dry state, the spawn, thus propagated, may lie till it be wanted in the autumn or following spring. If such pieces of spawn be continued in a dry state, the spawn will remain good for a long time."

3416. Another way, similar to the preceding, to make mushroom-spawn, is as follows: "Some time in the month of May or June, collect about eight or nine bushels of dung from the fields, or take it from the stables; separate it entirely from the straw; add to it six barrels of fresh loam, two barrels of soil scraped from the road, and one barrel of coal-ashes sifted fine; mix these well together; then spread the mixture on the floor of a dry shed, give it a gentle watering, and spread over it a quantity of spawn from an old mushroom-bed; after this, tread it as firm as possible, and continue to do so two or three times a-week. In this situation let it remain till it is turned into a solid mass of spawn, which generally is about the end of August; then cut it into lumps, and lay them up edgewise to dry."

3417. Microcrobe says, "Pieces of it may be laid along the ridge of a cucumber-bed raised in spring. Plant them about a foot apart. In about two months, the surface of the spawn will assume a mouldy appearance; it is then to be taken up with the earth adhering thereto, broken into pieces, and laid upon the shelf of a dry shed."
3418. Oldacre's mode of propagation is as follows: "Take any quantity of fresh horse-droppings mixed with short litter (as recommended for the beds), add one third of cow's dung, and a small portion of earth to cement it together; mash the whole into a thin compost, and then spread it on the floor of an open space, enough to form it to firm enough to be formed into flat, square bricks, which being done, set them on edge, and frequently turn them until half dry; then, with a dibble make one or two holes in each brick, and insert in each hole a piece of good old spawn, the size of a common walnut; the bricks should then remain until they are dry. This being completed, level the surface of a piece of ground through which the spawn may have run the length sufficient to receive the bricks, and level up six inches high; then form a pile, by placing the bricks in rows one upon another (the spawn-side uppermost) till the pile is three feet high; next cover it with a small portion of warm horse-dung, sufficient in quantity to produce a gentle glow to the spawn. When this is formed, cover the whole of the parts of the bricks, the process is ended, and they must be laid up in any dry place for use. Mushroom spawn, made according to this receipt, will preserve its vegetative power many years, if well dried before it is laid up; if moist, it will grow, and soon exhaust itself.

3419. An original mode of propagating spawn, practised by Hay, in Scotland. "A quantity of cow-droppings is to be gathered from the pastures; some rotten wood, or spray from the bottom of a hedge, is to be collected, with a little strong loam. These are mixed, and formed into a moist, ductile sort of mortar or paste, of such consistence that it can be cut into pieces like bricks. When these are dry, the bricks can be broken in the case, or can be laid down, and if the air be warm, in a shade at the back of a hot-house; a little spawn is placed upon the layer; then another layer of the spawn-bricks, and so on. In a few weeks the whole mass is penetrated by the spawn. The spawn-bricks may then be laid aside for use; they will keep many months; and the drier they are kept the more certainly do they afford a crop of mushrooms when placed in favorable circumstances for doing so."

3420. Roger's mode of preparing spawn is as follows:—I collect pure cow-dung, not fresh, but such as I happen to find in the park, the fields, or the farm-yard; with this I mix the scarpings of roads, in the proportion of one half to one, adding to it about one third or a fourth of vegetable mould, obtained from leaves or decayed stumps. These ingredients being well worked up together, the compost is formed into bricks about nine inches long, three and a half broad, and two thick. The bricks are exposed to the air and sun, and kept to attain a solidity of consistency, after which they become hard. They are then removed to a shed for the purpose of being laid up in strata. Three or four rows are first placed on the ground with interstices of about one inch in width between the rows and the bricks; into these interstices, or spaces, loose spawn, such as is found in the litter of old mushroom-beds, is scattered; and over the whole surface of the layer such spawn-litter is likewise spread. Should there be no old mushroom-beds at hand to furnish the scatterings, some spawn-bricks must be broken to pieces in order to supply them. The first layer having been thus treated, another is put upon it, and likewise interspersed and covered with spawn and litter from old beds. A third and fourth stratum may be laid on, or more, and regulated in the same manner. The whole pile being completed according to the quantity that is required, it is covered over with hot stable-dung and litter; and in two, three, or more weeks, according to the state of the weather, the bricks are filled with spawn, and may be laid by for use. I will not hazard an opinion, whether the composting itself, or only the increased temperature of a matrix, or receptacle; but this I can state, that mushroom-spawn is generated in other dung besides horse-dung; for I once found it plentifully in pigeon's dung. As I have used this preparation of spawn for a length of time, the essence of cow-dung must entirely preponderate in my composition; though the original form would at first appear to have been derived, I am so far mistaken in the manner I have described, it yields spawn as productive as any that can be obtained. I was formerly taught to believe that it was essential to mix a portion of horse-dung in the bricks, but my experience has taught me that it is not requisite, that cow-dung alone answers the purpose. The spawn is generated in it plentifully, and of good quality.

3421. Care of the bricks. It is of importance that the bricks alluded to should not be left in a situation which would cause the spawn to work, an effect which would be produced by moisture, combined with warmth. Therefore, when the spawn is bred, the bricks must be laid in a dry place to prevent the process of germination. The spawn must not be suffered to advance towards the rudiments of the mushroom, which consist in little threads or fibres, for in this state it ceases to be useful in spawning a bed. As soon as these rudiments are formed, they must be left undisturbed, or they perish. They will grow into a mushroom, where they are developed; but when removed or torn up, they are destroyed. A piece of spawn which appears in fibres or fibres is no longer applicable to a mushroom-bed; it may produce a mushroom in itself, but can serve no other purpose. The spawn that is to be inserted in a bed, and to produce the mushroom, must not be gone so far, but should only have the appearance of indistinct white mould. (Hort. Trans. vol. iv. 472.)

3422. The importance of keeping spawn dry is attested by Miller, who found, that spawn which had lain for four months near the furnace of a stove, yielded a crop in less time, and in greater profusion, than any other.

3423. The methods of rearing mushrooms are still more various than those of propagating the spawn. They are most commonly grown in ridges in the open air, covered with litter and mats; and next in frequency in ridges of the same sort under cover, as in the open sheds of hot-houses. They are also grown in close sheds behind hot-houses; in fluid beds built on purpose, or mushroom-houses; on shelves in fluid mushroom-houses; in pots, boxes, hampers, baskets, placed in any warm situation; in cucumber or melon beds; in old hot-beds of any sort; in pits with glass frames; and in dark frames or pits.

3424. Ridges in the open air. M'Phail says, "Some think that mushrooms do better in the open air than in covered sheds, which I have frequently experienced to be the case. In sheds, mushroom-beds are apt to become too dry; in the open ground, the humidity of the air, and a little wet sprinkling through the covering, keeps them in a damp state." (G. Rem. p. 110.)

3425. Preparing the dung. Provide good horse-dung, purged of its fiery heat by the usual preparation; with which some old linings from a melon-bed may be mixed, if it is not winter. (Abercrombie.) M'Phail says, "Take two cart-loads of fresh stable-dung, to which add an equal quantity of old dry linings from melon or cucumber beds, mixing them well together in a heap; and after letting it lie about a fortnight, it will be in a fit state to make into beds. To make a mushroom-bed of new dung, let the same be well prepared, by laying it together in a heap to ferment, and by turning and mixing it well, shaking the outside of the heap, which is cold, and the inside, which is hot, to-
gether, so that every part of it may be equally fermented, and deprived of its noxious quality."

3426. Forming the bed. Abercrombie says, "Mark out the ground-line of a bed four feet wide at bottom, the length to be governed by the quantity to be raised; from this, work with an inward slope, so as to terminate with a narrow roof-shaped ridge along the centre, three feet or more in height. In building the bed, shake and mix the dung well together; beat it down with the fork, but do not tread it: leave it to settle, and to expend the first heat in vapor. When the dung is in a fit state to make into a bed, which it will be in about three weeks or a month after it has been put together to ferment, let the bottom for it be marked out about seven feet wide, and as long as you choose to make it; let the foundation on which it is made be dry, and let it be worked up in a sloping manner, so as to terminate with a narrow roof-shaped ridge along the centre, about four feet or more in height. In making the bed, shake and mix the dung well together; beat it down well with the fork; and if the dung be long and dryish, tread it down as you proceed." (M'Phail.)

3427. Moulding the bed. "Having proved by trial-sticks left some days in the bed, that the heat is become moderate, you may cover two thirds of the sloping bank with mould two inches thick, leaving the top of the ridge open for the steam to evaporate as it gradually rises. When the exhalation is finished, the top may also be earthed over; or, earth round the bed four inches high, forming a ledge of mould two inches thick.

3428. Planting the spawn. "Divide the large cakes of spawn into small lumps. These may be planted in rows six or eight inches asunder. Place the lumps of spawn about six inches apart in the same row, inserting them through the mould close down to the surface of the dung: or, the dry spawn may be broken or scattered over the bed; being covered with earth to the depth specified above." (Abercrombie.)

3429. M'Phail directs, "When the bed has been some time made, and the heat sufficiently declined, the spawn may be put into it; but, for fear of the heat being too great in the upper part of it, it had best be all covered with one inch of soil before you put in the spawn. Take the spawn in small pieces, and stick it into the sides of the bed, in rows about three or four inches piece from piece, so that the spawn and earth about to be laid on, may meet. When the bed is spanned as high up as it is thought the heat of the bed will not injure it, take good, strong, rich earth, of a loamy quality, and cover the spanned part of the bed with it, about two inches thick, beginning to lay it at the bottom of the bed, beating it firm with the spade. The earth should be in a pliable state; not wet, nor over dry."

3430. Covering the ridges. "The inconvenience of a bed exposed to the weather, is, that it is sometimes necessary to cover it from wet, where there is danger of thus exciting a fermentation. When the bed is even under a shed, it is necessary to apply a covering from three to twelve inches thick, as the strength of the dung declines, or as the bed may be exposed, at the sides, to rain, snow, or frost. The covering may be either clean straw and long dry stable-litter, or sweet hay and matting; the latter is to be preferred. Lay it thin at first, and increase it as circumstances demand."

3431. Rivers in open sheds are formed and planted exactly in the same manner.

3432. In rearing in close sheds or hot-houses, where the temperature approaches to 50 or 55 degrees in the winter months, from the heat arising from the hot-house furnaces, the ridge mode above may be adopted, or a flat bed similarly composed and planted.

3433. In flued sheds, or mushroom-houses on the common plan, the method of forming the dung-bed, earthing, and planting is the same as in the last modes sometimes; however, the beds are formed in a walled pit, and flat, or sloping, on the surface, like a cucumber-bed.

3434. German mode of cultivating the mushroom. The culture of mushrooms on shelves, in flued sheds or houses, is a German practice, introduced to this country by Oldacre. The plan of Oldacre's house has been already given (figs. 279. to 281.) M'Phail describes a similar one, "as a good method of propagation." (Gard. Rem. p. 108.) To either houses the following directions will apply: —

3435. Compost for the beds. Collect a quantity of fresh horse-dung, that has neither been exposed to wet nor fermentation, clearing it of the long straw, so as to leave one fourth, in quantity, of the shortest litter, when incorporated with the horse-droppings; then add a fourth part of tolerable dry turf-mould, or rather maiden earth, and mix it well with the dung before mentioned: the advantage derived from the mould or maiden earth is the union of the whole into one compact solid substance, so congenial to the growth of mushrooms. If dung from the sides of a livery-stable, or the round of a horse-mill, can be procured, and added, and also a fourth part of fresh horse-droppings as will cause a gentle warmth, when made into beds, it will be found superior, for the production of mushrooms, to horse-dung that is gathered from the stables.

3436. Spreading out of mixing the compost. Remove the compost from the beds on the shelves and ground-floor by placing a layer about three inches thick of the prepared mixture. Then, with a flat mallet, beat it as close together as possible, next add another layer of the compost, repeating the same process as before, and so on until the beds are formed into a solid body, seven inches thick, making the surface of the beds as smooth and as even as possible. The reducing the beds into a very solid body is a most essential point; for, without it, you cannot expect success; and the thickness of them must also be particularly attended to; for, where there is much a greater body, the beds will be subjected to a strong fermentation, and will be prevented, by evaporation, from retaining that consistency in the dung, which is absolutely necessary for the production of good and plentiful crop. On the contrary, if a much less quantity be laid together, the heat and fermentation will be insufficient to prepare the beds for the nourishment of the spawn; but the assistance
of both, to the extent prescribed, cements the materials together, which, in addition to heating, increases greatly their solidity. The proper vegetation of the spawn, and the consequent crop of mushrooms, depend entirely upon a moderate genial heat and fermentation, neither too strong nor too slight. As soon as a bed is made, take a liberal quantity of spawn, mix it in the beds with a little more than that of milk from the cow, (say from eighty to ninety degrees of Fahrenheit's thermometer) and let the beds, without heat, remain for a few days, then make holes with a dibble, three inches in diameter, and nine inches asunder, through the compost in every part of the beds: these holes will be a means of cooling the beds, and preventing that excess of heat from occurring which would produce decay. In about a week, or when the moisture is sufficient to attain the heat required, in four or five days after they are put together, (which you will know by plunging a thermometer into one of the holes,) add another layer of the compost, two inches thick, which will probably increase the heat sufficiently; if not, a part of the bed should be taken away, and the remainder made up by the compost and spawn. In this manner, and with care, you may easily produce the proper degree of heat. Beds made after this manner readily generate natural spawn in summer, and frequently in the winter months.

3437. The beds. In three or four days after the holes have been made, by observing the thermometer, it will be found that you have the desired degree of heat, and the inside of the holes will also have become dry: the beds are then in a good state for spawning, which should be done while the heat is on the decline. If this operation be deferred until the heat is quite exhausted, the crop will be late, and less plentiful. The moist hole will be made up, which, if not done, results in cutting the surface of the beds solid and level; it is of no consequence whether the spawn put into the holes be in one lump or in several small pieces, it is only necessary that the holes should be well filled. About a fortnight after the spawn has been introduced, examine the holes, and if the spawn has suffered any damage from overheat, or too much moisture, in the beds, introduce fresh spawn in the same way as before. On the contrary, if the spawn be found good, and vegetating freely into the compost, such beds (if required for immediate production,) may be covered with mould agreeable to the rules hereafter laid down; and the beds intended for succession should remain uncurried, in the summer, three weeks or a month before you wish them to produce, and in the winter a month or five weeks. If the spawn be introduced in hot weather, air must be admitted as freely as possible into the shed, till the spawn has spread itself through the beds; for if the place be kept too close, the beds will become soft and spongy, and then the crop will neither be good, nor of good quality, in order to proceed.

3438. Of earthing the beds. Such beds as are intended to be put into work, must be covered with a coat of rich maiden earth, wherein its turfs is well reduced. Then spread it regularly over the surface of earth, and throw back; and this will solid and harden, as all those that take a little dry, nor yet wet, but so as to become compact together, and take, when beaten, a smooth face. If too moist, it will chill the beds, and injure the spawn. On the contrary, if too dry, it will remain loose, and in a state by no means favorable to the growth of the mushrooms: but when solid, it produces not only finer mushrooms, but in greater quantities, as the earth, from soils of lighter texture invariably grows them weaker, and of inferior quality, and such beds cease bearing much earlier.

3439. Of the subsequent treatment. From the time of covering with earth, the room or shed should be kept at fifty to fifty-five degrees of Fahrenheit's thermometer, and the light must be excluded. If the heat be sufficiently to exceed, to any considerable degree, it warms the bed too warmly, and no account will be made, if not totally destroy, the spawn; but should a much lower degree of temperature than the one prescribed be permitted to prevail, the mushrooms will advance slowly in their growth; and if watered in the second week, the small degree of temperature, the mushrooms, in the extreme case, is as well, as in the mode of application, as in the temperature of the water, which should be nearly as warm as new milk, and very lightly sprinkled with a syringe, or a small watering-pot; otherwise the mushrooms are sure to sustain damage. If cold water be used, and given plentifully at one time, it will not destroy the existing crop, but the spawn also, and render the beds so treated of no further utility. If the beds have been suffered to become very dry, it is better to give them several light waterings than one heavy supply. In gathering the mushrooms, great care should be taken not to disturb the small ones that invariably, with good management, surround the stems of those which are more early matured. The best method is to twist them up, very gently, in all instances where you can. But where you are obliged to cut them, great care should be taken to divest the beds of the stems of those that are cut, as they would rot, to the great injury of those that surround them. If the preceding directions are properly followed, and the beds, in the management of the bed-crop, be kept to a moderate and constant supply may be kept by earthing one bed or more, every two or three months, according to the quantity of mushrooms required at one season. When the beds are in full bearing, if the mushrooms become long in their stems, and weak, it is certain the temperature of the building is too high; consequently, it is admitted in partial, and to the heat.

3440. Of renovating the old beds. As your beds begin to decline in bearing, and produce but few mushrooms, take off the earth clean from the dung, and if you find the latter decayed, destroy the beds and replace them with new. If the dung is not decayed, in a few weeks the old spawn will be destroyed, and the earth becomes sweet and rich, while the new is in full bearing. Away the earth, you find the beds dry, solid, and full of good spawn, add a layer of fresh compost, as before recommended, three or four inches thick, mixing it a little with the old, and beat it as before. By adhering to this mode of renovating the old beds, a continual supply may be kept up. (Oldacre, in Hort. Trans. vol. ii.)

3441. Estimate of the merits of the German mode of cultivating mushrooms. Neill observes, "In what particulars the advantage of Oldacre’s plan over former modes chiefly consists, does not very clearly appear. Beds made up in the usual way are much less compact, and are more damp; compactness and dryness may therefore be considered as important." (Ed. Encyc. art. Hort.) Rogers remarks that "the quantity of mushrooms depends upon the manner in which they are nourished: if they are meagerly fed, their flavor and substance will be poor in proportion. Hence artificial mushrooms are, generally, richer and higher flavored than those which grow naturally; and again, among the artificial produce, those will surpass which are reared on large and deep beds." It is a fact, that in Covent Garden market, mushrooms grown on ridges are greatly preferred to those grown on shelves, or in boxes, in the German manner: they are considered heavier and more juicy. (Hort. Trans. iv. 475.)

3442. Growing mushrooms, in pots, boxes, &c. with dung, by Wales. "Having given an account how to procure the spawn, which is the principal point, I shall next proceed to state how mushrooms are to be raised from the spawn with dung. I raise the mushrooms in boxes, hampers, or, in short, in any thing which will hold the dung and the soil together. These boxes or vessels are placed in the back sheds of the hot-houses, or in any house whatever, where no dam nor frost can enter. There should be several boxes, a part only being filled at a time, so as to keep a rotation of them, and have mushrooms
at all times ready for the table. I shall suppose three boxes to be filled at one time. Each box may be three feet long, one and a half broad, and seven inches in depth. Let each box be half filled with horse-dung from the stables (the fresher the better, and if wet, to be dried for three or four days before it be put in the boxes); the dung is to be well beat down in the boxes. After the second or third day, if any heat has arisen amongst the dung, it is then a fit time to spawn: break each spawn-brick into three parts as equal as possible; then lay the pieces, about four inches apart, upon the surface of the dung in the box; here they are to lie for six days, when it will probably be found, that the side of the spawn next to the dung has begun to run in the dung below; then add one and a half inch of more fresh dung upon the top of the spawn in the box, and beat it down as formerly. In the course of a fortnight, the box will be ready to receive the mould on the top; this mould must be two and a half inches deep, well beat down with the back of a spade, and the surface made quite even. But before the box be earthed over, it will be proper to take up a little of the dung, as far down as near the bottom of the box, to see if the spawn has run through the dung; if not, let the box stand unheated for some days longer, for, were it to be earthed before the spawn had run through the dung, there would be put a poor crop. In the space of five or six weeks the mushrooms will begin to come up; if then the mould seems dry, give a gentle watering, the water being slightly heated in any warm place before applied. This watering will make the mushrooms start freely, and of a large size. I cut three myself, which weighed 18\(\frac{1}{2}\) oz. from a box treated as above. The boxes will continue to produce for six weeks, and I have had them productive sometimes for two months, if duly attended to, by giving a little water when dry, for they need neither light nor free air. I have had thirty-two pretty well-sized mushrooms in one cluster. If cut as button-mushrooms, each box will yield from six to twelve Scots pints (24 to 48 Eng. pints), according to the season and other circumstances. The plan now described, I prefer for yielding numbers of mushrooms, and where a great many are required; but when reared without dung, they are best flavored. They are not then to be distinguished from those which grow naturally in the fields, but comparatively few are in this way produced. I have lately found it very useful to add to every three barrow-loads of horse-dung, one of perfectly dry cow-dung, beat down to powder as it were, and well mixed among the horse-dung, after the horse-dung has lain under cover for four or five days to dry. The reason I tried the cow-dung dry was, that I still found the horse-dung to have a strong damp, after having lain in the boxes for some time; but the cow-dung, when beat down to powder, has the effect to dry up this damp, and also to make the horse-dung lie in the box more compactly; and the more it is pressed down, the finer the spawn will run amongst it."

(Wales, in Caled. Hort. Mem.)

3443. Growing mushrooms, in pots, boxes, &c. without dung. "Take a little straw, and lay it carefully in the bottom of the mushroom-box, about an inch thick, or rather more. Then take some of the spawn-bricks, and break them down, each brick into about ten pieces, and lay the fragments upon the straw, as close to each other as they will lie. Cover them up with mould, three and a half inches deep, and well pressed down. When the surface appears dry, give a little tepid water, as directed for the last way of raising them; but this method needs about double the quantity of water that the former does, owing to having no moisture in the bottom, while the other has the dung. The mushrooms will begin to start in a month or five weeks, sometimes sooner, sometimes later, according to the heat of the place where the boxes are situated. They do not rise so thick nor of so large a size, nor do they continue to be produced so long, as in the other plan with dung." (Wales.)

3444. Compost or mould for growing mushrooms in boxes. "Take a quantity of horse-dung from the stable-yard fresh, and for every layer of dung, six inches in depth, lay three inches of fine earth from any light soil; these alternate layers may be repeated till there be as much as will probably be wanted for the course of a year. After this mixture has lain about six months or so, the dung will be sufficiently rotten: it should then be well broken with a spade, and passed through a garden-sieve. Two inches of this compost laid upon the top of the box, and well pressed down with the back of a spade, will be found to answer. It is to be understood, that the same compost, made of the dung and earth, is used for going on the top of the beds formed with dung, as well as on those without it, observing to have it sifted fine, and well dried, for if it be damp, the spawn would not run freely amongst it." (Oldacre, in Horticultural Transactions.)

3445. Culture of the mushroom in melon-beds. The following mode has been practised by the Rev. W. Williamson, for several years, with great success. He considers it more economical and generally practicable than the plan of Oldacre. "Having made my melon-bed in the usual manner, when the burning heat is over, and the bed is ready to be earthed to a sufficient thickness, I place spawn on the sides of the hills, and also on the surface of the bed, and then cover the whole with mould, as usual, managing the
melons exactly in the same manner as if the spawn were not there, not omitting even to tend it, as I find that a compact loam is more congenial to the growth of the mushrooms, than the light rich compost of the cucumber-bed. The heat will soon cause the spawn to run, and extend itself through the dung, to the surface of the ground. In September or October following, when the melon-bine is decaying, the bed is carefully cleaned, the glasses are put on, and kept close; and when the mould becomes dry, it must be frequently watered, but not immoderately, as too much wet would destroy the spawn; advantage should also be taken of every gentle shower, for the same purpose. The moisture coming up on the dry earth produces a moderate heat, which soon causes the mushrooms to appear in every part of the bed, in such abundance as even to prevent each other's growth. I have frequently, at one time, gathered two bushels from a frame ten feet by six, and have produced individual mushrooms of nearly two pounds' weight. The mould being kept warm by the glasses, and properly watered, the mushrooms will continue to spring till the frost of winter prevents their further growth. I then leave the bed, frame, &c. just as they are, and early in spring, as soon as the frost may be supposed to be over, I take off the frame and glasses, and cover the bed lightly with straw; when the warm enlivening showers of spring cause the mushrooms to be again produced in every part, till the drought of summer renders it difficult to keep the bed sufficiently moist for their growth. Sometimes I suffer the bed to remain, in order to produce a crop in the second autumn, but more generally take the bed to pieces, for the sake of the dung, and also for the purpose of procuring and drying the spawn, against the return of spring. When I first thought of raising mushrooms in the manner above described, I was apprehensive, lest the spawn, by running among the roots of the melons, might injure their growth. I therefore planted it in one light only, but the result convinced me that it did no injury, as, on the only plant in that light I grew a melon, of the black rock kind, weighing eight and three quarters pounds, for the first crop, and another six and a half pounds for the second crop; both of which ripened well. Since that time I have always placed the spawn over the whole of the bed, and have never failed to produce a good crop of both melons and mushrooms. Should it be thought advisable to have a supply of mushrooms during the depth of winter, I am confident (though I have not tried the experiment,) that they might be obtained, at a trifling expense, by lining the bed with hot dung, and using other precautions to keep out the cold air." (Hort. Trans. v. iii.)

3446. Oldacre, at the end of his paper on growing mushrooms on shelves, &c. says, "They may be grown also plentifully, in hot-bed frames, by the same process as is recommended for the sheds. In this latter practice, as soon as the beds are earthed, they should be covered with hay or litter under the lights, until they are in full bearing, then remove the covering to the outside of the lights, to exclude the sun and air as much as possible. In cold weather, if they advance slowly in their growth, the frames may be covered with hot dung, which will greatly encourage them. It must be recollected, that when these beds are made in hot weather, air must be admitted as freely as possible into the frames, during the time of spawning, as directed for the management of this part of the process, in cellars or sheds."

3447. In old hot-beds. A good crop of mushrooms is sometimes obtained without making a bed on purpose, by introducing lumps of spawn along the margin of late cucumber-ridges, just into the top of the mould. This may be done from March to May. (Abercrombie.)

3448. In pits. Jeeves has adopted this practice, and thus describes it. "To make my bed, the dung was placed in the bottom of the pit, and rammed tightly down, to about the thickness of eighteen inches; the dung itself producing sufficient heat to set the spawn running, after it had been introduced in the usual manner. The bed was made up last September, and came into bearing in six weeks; it has continued to produce regularly to the present time, and requires no more heat than is collected by the effect of the sun on the air within the house, except on frosty nights, when a little fire is put into the flue. The mushrooms come up uniformly over every part of the bed, which is covered very slightly with straw, (not sufficient to exclude the light,) for the purpose of preserving moisture on the surface."

3449. In dark frames. Nicol says, "If you have no mushroom-house, and yet are anxious to have mushrooms in winter, a cover or frame, capable of defending the bed from rain, snow, or frost, may be made at a small expense, thus: first, make a frame of inch-and-half deal, nine or ten inches deep, six feet wide, and of any convenient length, ten to twenty feet. Then fit a roof to it, three feet in the pitch, made of thin boards, imbricated, which lay over with two or three coats of pitch or paint. The roof part to be fixed down to the wooden frame by hooks and eyes, or by bolts, so as that it may be removed at pleasure, and to have two moveable boards on each side, of about a foot square, to slip for the admission of air. This sort of frame being placed in a dry warm situation, and being insulated by a drain or trench, would completely defend the bed from wet; and by being covered, in severe weather, with straw or mats, from frost. If the ground be not perfectly dry, a sole or floor must be formed of ashes, gravel, or stone-chips, for the bed; a thing necessary in any situation which is the least damp, either within or out of doors."
3450. In a cellar. "Mushrooms may likewise be produced in a cellar, or any other vaulted place, with equal success, and not unfrequently to greater advantage as to crop, than in a shed, or other building, that is level with the surface of the earth. The same rules of management are to be observed as directed for the shed. The peculiar advantage of a cellar is, that no fire is necessary, and less water, the application of which so frequently proves injurious, is wanted."

3451. On hollow ridges. Hogan says he has devised an easy mode of growing mushrooms under shelter, and tried it one season with great success. "The exterior form of my bed resembles the old ones as built against a wall; but instead of building it solid, it is hollow; strong stakes are inclined against the wall, at an angle of about 65°, on which are placed hurdles to support the bed. By this means a cavity is formed under the stakes, between them and the wall and floor, for the purpose of receiving dung, which being readily changed, an opportunity is thus afforded of keeping up a permanent moist heat in the bed, the absence of which, together with an insufficient depth of mould for the spawn to run in, is the great defect of all other modes of raising mushrooms with which I am acquainted. On this structure fourteen inches of rotten dung and four inches of loamy earth were laid, and beat firm, and the spawning and other processes and results were the same as usual." (Hort. Trans. v. 305.) We fear two things from this mode—occasional overheating and overdrying, either of which are as ruinous to the mushroom, as they are to cape-heaths in pots.

3452. The following details of culture are common to each of the above modes of rearing the mushroom:

3453. Season for commencement. Mushroom-beds or boxes may be formed and planted at any time of the year; but the month of September is the most natural season; and the time next to be recommended is early in spring. In June, July, and August, the weather is rather too warm; and in the depth of winter, it is too equally cold to excite and cherish the spawn. (Abercrombie.) Nicol makes up a bed in March to last till September, and another at that time to last through the winter, till the bed to be again made in March comes into existence. He adds, however, that there is no rule for making up these beds, as it may be done at any day of the year with nearly equal propriety. (Kalender, p. 30.)

3454. Time of growth. In autumn and spring, common ridges will often begin to produce plentifully in four, five, or six weeks. In summer or winter they are much longer before they become productive. (Abercrombie.) In Wales's method of growing in boxes, they come up in five weeks. Abercrombie says, mushroom-beds have been known to lie dormant for five or six months, and yet afterwards produce abundant crops. Where a bed is cold, Nicol observes, it will be sometimes two or three months of producing mushrooms.

3455. Symptoms of progress. Nicol says, when you would know whether the spawn has begun to run, thrust your hand a few inches deep into different parts of the bed, and examine what you bring up. If it smells exactly of mushrooms, and has the appearance of bits of thread, then the spawn is in action. "But generally you will be forewarned of the spawn's running, by a previous crop of spurious fungi, which rise more or less abundantly, according to the fineness or grossness of the materials of which the bed is composed. These fungi generally are either what are called pipes or balls; and sometimes a kind of mushroom, of a very bad sort, thin, flat, with white or pale yellow gills. They have all, however, a nauseous, sickly smell, and may readily be distinguished from the true mushroom, which is thick, hemispherical, with brown or reddish gills."

3456. Duration of a crop. Six months is the ordinary duration of a common bed or ridge, made in the open air or in a filled shed. Oldacre says, his beds will continue to produce for several months. To have a succession, he earths a bed every two or three months. Wales's boxes (3442) continue to produce for six weeks, and sometimes two months.

3457. Temperature. Nicol says, if the bed be placed in a filled shed, the temperature in winter should be kept steadily to about 55 degrees. This is also Oldacre's temperature.

3458. Wales says, "I have ever found the best adapted and most productive heat to be from 55 to 65 degrees, and the nearer the beds are kept to this heat the greater will be the success."

3459. Air is essentially necessary to the flavor of mushrooms. Oldacre says, air must be admitted in proportion to the heat, otherwise the mushrooms become long in their stems, and weak. The same thing takes place in ridges when the coversings are too thick.

3460. Water. Abercrombie and Nicol agree in recommending no water to be given till the spawn begins to run.

3461. Abercrombie says, "In autumn, the bed will want no water until the first crop is gathered. Then a sprinkling will help to excite a fresh vegetation. In spring, should a drying air long prevail, it may be necessary to moisten the bed a little. In summer, the bed may be now and then exposed to gentle showers, and especially to keep down the dryness and heat of the season. In order to give water, without wetting the bed excessively or unequally, scatter a thin layer of short hay over the ridge; and let a small quantity of water be gently distributed, to all parts alike, from a rose-pan. Leave it to filter through the hay, and cover the bed up with litter. In winter, the substitute for watering must be some warm water from a dung heap, laid over the dry litter; the moisture evaporating from this will promote the growth of the mushrooms. Excessive moisture is not only apt to destroy the spawn, but it debases the flavor of such fungi as can be produced under it. It is also supposed to render the salutary sorts less so, and some of them insipid and unwholesome."

3462. Nicol says, "When the spawn is fully formed, give the bed two or three hearty waterings, in order to set it a growing; for, otherwise, it will lie dormant, and show no symptom of vegetation. Give just as much water (but with no means at once) as will fairly reach to the bottom of all the boxes. Afterwards keep the bed in a state neither wet nor dry, but rather inclining to the latter, this being the safe side to err on, as it is more easy to make it damp than to dry it. When a bed has been, as it were, tired of producing, I have sometimes desisted from watering for several months; then by examination I have found a new net of spawn formed all over the surface, the threads being deep-rooted, even to the
bottom. By a hearty watering, as above, a most plentiful and lasting supply has been obtained. The idea of treating my beds so, arose by observation of the manner in which field-mushrooms are often produced. We frequently see the crop suddenly disappear, and as suddenly appear again, according to the state of the weather, with respect to wet or drought; and that too, in the same field."

3465. Light. Abercrombie, Nicol, and most gardeners and authors, consider light as quite unnecessary for the production of the mushroom. It is very probable, however, that it contributes in some way to their perfection, since in their natural situation, they enjoy a considerable portion of it. Our opinion is, that it should not be entirely excluded from mushroom-houses or beds on whatever plan they may be constructed. See an interesting proof of value of light in Chaplet’s *Agr. app. à Chimie*, vol. i. p. 180.

3466. Gathering the crop. When the bed is in full production, and the season fine, mushrooms may be gathered two or three times a-week. Turn off the straw covering, and return it carefully at each gathering. (Abercrombie.) “In gathering mushrooms,” Nicol observes, “they should always be cut, and never be pulled; as by pulling, many young ones might be destroyed. There are always a number of these forming or clustering about the roots of the old ones, which should not be disturbed. If the spawn be deeply situated in these beds, mushrooms will often form and come to full maturity, entirely under ground. They may easily be recognised, however, as they are generally large, and push up small hills above their heads. They ought to be uncovered with care, that the spawn about them may be as little disturbed as possible.” Oldacre says, in gathering mushrooms, avoid disturbing the small ones, that invariably, with good management, surround the stems of those which are more early matured. Twist them up very gently in all instances where you can; and when obliged to cut them, take care to divest the beds of those that are cut, as they would rot and injure those around them.

3467. Poisonous mushrooms. For the characters of the true mushroom (*Agericus campytris*), and the other species and varieties, edible and deleterious, see the following chapter. Their duration is too fugitive to admit of their being much injured by insects.

---

**Chap. VIII.**

**Horticultural Catalogue. — Hardy Herbaceous Culinary Vegetables.**

3468. The various plants and trees grown in the different departments of horticulture shall now be more particularly enumerated and characterised, and some account given of their history, use, and culture. We shall commence with the hardy herbaceous vegetables; and the most suitable arrangement for this class of plants seems to be, that arising from a combined view of their habits, culture, and uses, in domestic economy. Though no such arrangement can be absolutely perfect, from the circumstance of some of the plants being used for different purposes, yet, by bringing together such as present most points of union, something better than a mere alphabetical catalogue is formed, of which the following is the outline:

3469. The cabbage tribe; comprehending the white and red cabbage, cabbage-colewort, Savoy, Brussels sprouts, borecoles or winter greens, cauliflowers, and broccoli.

3470. Leguminous plants; comprehending the pea, bean, and kidneybean.

3471. Esculent roots; comprehending the potatoe, Jerusalem artichoke, turnip, carrot, parsnip, red beet, skirret, scorzonera, salsify, and radish.

3472. Spinaceous plants; comprehending the garden-spinage, white beet, oracle, wild spinage, New Zealand spinage, sorrel, and herb-patience.

3473. Alliaceous plants; comprehending the onion, leek, chives, garlic, shallot, and rocambole.

3475. Accetarious plants or salads; comprehending small salads, lettuce, endive, succory, dandelion, celery, mustard, rape, corn-salad, garden-cress, American cress, winter cress, water-cress, brook-lime, scurvy-grass, garden-rocket, burnet, buckshorn plantain, ox-eye daisy, and some of those included in other sections, as the sorrel, tarragon, Indian cress, &c.

3476. Pot-herbs and garnishings; comprehending parsley, purslane, tarragon, fennel, dill, chervil, horse-radish, Indian cress, marigold, borage, and some others included in other sections.
The cauliflower, and B. Ileaves in the from 607 Kopfkohl, varieties is roots a leaves favorite B. sprouts, flower-buds into SuBSECT. Cabbage into the Saxons; for they named the month of February Sprout kale. Being a favorite with the Romans, it is probable the Italian cabbage would be introduced at an early period into South Britain. To the inhabitants of the north of Scotland, cabbages were first made known by the soldiers of the enterpriseing Cromwell, when quartered at Inverness. (Edin. Encyc. art. Hort.)

The original cabbage-plant grows naturally on the sea-shores in different parts of England, but it has not been observed in Scotland. It is a biennial plant; the stem-leaves are much waved and variously indented; the color is sea-green, with occasionally a tinge of purple. Early in the spring, the wild cabbage or colewort, from the sea-coast, is said to be excellent, but it must be boiled in two waters to remove the saltiness. The roots may also be eaten, but they are not very tender. (Neill, in Ed. Encyc. and Martyn, in Mill. Dict.)

A new arrangement of the cultivated species of brassica has been made by Prof. Decandolle (Hort. Trans. vol. i., and in his Reg. Veg.), but as many of the varieties which the brassica oleracea assumes on the continent are little known here, and as some of our varieties are omitted in Prof. Decandolle’s enumeration, there does not seem at present any sufficient reason to deviate from the usual British arrangement of this genus. Prof. Decandolle’s varieties, or races, of B. oleracea, are—

| B. oleracea sylvestris, or wild cabbage | B. oleracea capitata, headed or leaved cabbage |
| acerana, open cabbage, or borecole | caulo-rapa, turnip cabbage, and |
| bullata, blittered cabbage, or Savoy | botrythia, flower-cabbage, or cauliflower, and broccoli. |

The cauliflower of the Dutch, he marks as a distinct species (B. capparums), and also the turnip (B. Rapa), the rape (B. Napet), and the summer rape of the Germans (B. prence).

The space occupied by this tribe in most kitchen-gardens may be estimated at one eighth part of the open compartments, taking the whole year round; and in cottage-gardens, the heading cabbages and borecoles generally occupy one half of the whole space. We shall take the varieties in the order of white cabbage, red cabbage, Savoy, Brussels sprouts, borecole, cauliflower, and broccoli.

The common or white garden-cabbage is too well known, and its uses too universal, to require any description. It produces firm, compact heads, glaucous, green, or greenish-yellow externally, but blanched within, and varying in different sorts from three to twelve or fifteen inches’ diameter, and from two to fifteen or twenty pounds’ weight.

Subvarieties. These are very numerous: the sorts chiefly cultivated are—

| Small early dwarf Essex dwarf York Early dwarf York Large early York Early dwarf suag-loaf East Han Early flattera or Early Imperial Pentonville | Large round head; leaves white and fleshly, wrinkled like the Savoy; very delicate and fine; in perfection during the latter summer months; when the other cab bapuses are of strong flavor. |
| Large round winter (white) | Great drum-head flat-topped Great round Scotch, or white Strasbourg; from which the German sour krotz is chiefly made. |
3489. Estimate of sorts. The first five or six sorts are suitable for the earliest and secondary summer crops; and the middle-sized and large kinds for the principal summer, autumn, and winter supplies. Thus, 1. For the earliest crops, allot some of the small early dwarf York, East Ham, and sugar-loaf, for early May and June, and for about four months in the case of the middle-sized kinds, particularly the large York, and large sugar-loaf, or the Battersea, Fenton, Imperial, Antwerp, and American kinds, &c. for general summer crops. 3. Choose the larger later sorts for succession, summer, and general autumn cabbages. The large hollow sugar-loaf, oblong hollow, long-sided hollow, and large round winter (white), and Russian, are the best cabbages in August, September, and October, for the purpose of filling large-sized varieties may be eligible sown for latter succession crops in summer and autumn, to cut in light young growth; also to cultivate for cabbage-collards, either with small hearts, or as open greens for family and market supply in autumn, winter, spring, and returning summer. 4. The large round winter cabbage, grown by English and American kinds, all reaching a very expanded bulk in autumn and winter, are not usually so well fitted for family consumption as the foregoing, being more commonly adopted for field-culture, to feed cattle in winter, &c.

All the kinds are raised from seed annually, of which, according to Abercrombie’s seed estimate, * for a seed-bed to raise the early York, and similar varieties, four feet wide by twenty in length, two ounces’ will be required. For a seed-bed to raise the large sugar-loaf, and other luxuriant growers, four feet by thirty-six in length, two ounces. Sow at three different seasons, that is, in summer, autumn, and winter, and cover with a thin layer of soil, to the eighth part of an inch over standing young plants, for final transplanting in spring, or, in order to have some spring-sown plants as forward as possible, a moderate portion of some best early sorts may be sown between the middle of February and the middle of March, in a slight hot-bed or frame, to nurture the plants till the leaves are about one or two in length. Then sow them into intermediate beds in the open garden, there to gain strength for final transplanting. (Abercrombie.)

3491. Soil and situation. The soil for seedlings should be light, and, excepting for early sowings, not rich. Where market-gardeners raise great quantities of seedling-cabbages to stand the winter, and to be sold for transplanting in spring, they choose, in general, the poorest and stiffest piece of land they have got, more especially in Scotland, where large autumnal sowings of winter drum-head and round Scotch are annually made, and where the stiffness of the soil gives a peculiar firmness of texture and hardness of cabbages, which are the best for the winter, their being kept in a frosty winter. Transplanted cabbages require a rich mould, rather clayey than sandy; and, as Neil and Nichol observe, it can scarcely be too much manured, as they are an exhausting crop. Autumnal plantings, if well watered and the wind in the spring, will have a decided good effect on the crop. The cabbage tribe, whether in the seed-bed, or final plantation, ever require an open situation. Under the drip of trees, or in the shade, seedlings are drawn up weak, and grown cabbages are meagre, worm-eaten and ill-flavored.

3492. Early and main summer crops. The cabbage being a biennial, the largest crops are obtained by sowing the year previous to that in which you expect to reap. Sow, therefore, at the beginning of August, to raise plants to stand over the winter in young open growth, for cabbaging early, and in succession, the following year. A nice attention should be paid to the time for sowing this crop, which is the first or second week in August, being that most conducive to ultimate success, though some sows at the close of July, to have the plants stronger before the approach of winter; but of a crop so far, many generally run for seed in the spring; therefore be careful to make the principal sowing neither sooner than about the fifth, nor later than the twelfth, of that month. For, if sown earlier, many of the plants are apt to run in the spring, as just stated; and, if sown later, they would not acquire sufficient strength before winter, to enable them to stand severe weather so effectually as those a little advanced in firmer growth.

3484. Sow each sort separately in an open free situation, in beds of rich mellow earth, broad cast, moderately thick, and rake in the seed evenly, lengthwise each bed. Give occasional watering, if dry hot weather; or sometimes shade with mats, in hot sunny days, till the plants come up fully; after which, continue the same method, whether a dry season, &c.

3485. When the plants have two or three leaves an inch or two broad in September, or beginning of October, lift some considerable portion from the seed-beds, and prick into beds of good earth, about four inches apart, giving water: all these are to remain in the intermediate bed during winter, to gain strength for transplanting in the spring. Those left in the seed-beds will thus have more room to advance evenly for transplanting the most forward of the early sorts in the same year, towards the end of October, or in November and December, and the principal supply in the spring, the last fortnight of February, or in March and April.

3495. In transplanting, continue to keep each sort separate, allotting the whole good ground; and, if dunged, it will be repaid in the crop. Plant some of the dwarf early in rows, from a foot and a half to two feet asunder, to admit of thinning for use in a young cabbaged state: those of the middle-sized, intended for autumn, and winter, in two feet, and a half to a yard asunder, and a half plant at least from two feet and a half to a yard asunder, giving water at planting in dry warm weather.

3496. In their subsequent growth, if any fail or run to seed, be careful to pull them up directly, and supply the deficiencies with fresh plants. As the crop proceeds, give it two or more timely hoeings, both to root out weeds, and to lessen the growth, thinning the plants, drawing some earth round the stems, which will strengthen and forward them considerably.

3497. If the different sorts will cabbage in succession from April till October. Some may be forwarded in cabbaging by tying the leaves together, moderately close, with osier twigs, or strings of bass. The succeeding main crops will not need that assistance, but will head spontaneously in due time. Of the earlier dwarf kinds, some probably will be fit for cutting, in small cabbage heads, at the close of April or beginning of May; and the others in full growth from May till July; and the succeeding main crops in full head to the end of October.

3498. Early spring-sown crop. To succeed the crops of the preceding autumn sowing, it is requisite to sow in the spring, to raise plants for use the same year, partly as young summer cabbages, and partly with for winter. As this purpose, for this purpose, by the beginning of April. A few for early summer use may be sown in the third week of February on a slight hot-bed, or on a warm border under glass. In case no plants were raised the preceding autumn, or if the young crop which has stood the winter be much cut by severe weather, there is an additional motive for sowing a few in the spring, of dwarf, middle-sized, and large kinds, according to the above estimate of sorts. Sow the different kinds separately, and in the same method as directed for the crop to stand the winter. Manage the plants in the seed-bed, and prick a proportion into an intermediate bed in the same manner. When of suitable growth for final transplanting, in May, June, or July, (taking opportunity of moist weather, if it occurs,) plant them out in rows traced from one to two feet asunder for the dwarf and middle-sized, and for the larger kinds from two feet and a half to a yard distant. Give water at planting.
In their subsequent growth, give occasional hoeing to kill weeds, and to draw earth round the stems, as advised for the August-sown plants.

3504. Sowing, thinning, and transplanting. For late young summer and autumn cabbages and winter plants, you may sow small portions at any time from May to July, principally of the quick-heating kinds; plant out finally in summer and autumn to produce young heads, and small cabbage-heated coleworts in August, September, October, and into the following winter. The large late family cabbages, which make returns in autumn, winter, and early spring, also the largest kinds usually adopted for field-culture, are to be excluded from this sowing, as they are only properly raised as part of the principal crops sown in August and early in spring. (Abercr Carm.)

3505. Taking the cabbage crop. After cutting off the head, never neglect immediately to pull up the stalk, and clean off with the knife the loose leaves of the post-hoar. This practice is enjoined as well to prevent the stem from pushing out shoots, and needlessly exhausting the ground, as to promote neatness and order. It is necessary, however, to make an exception in favor of the practice of some, who, instead of removing the roots and stems of the main summer crop, leave them in the ground deprived of their injured leaves, and allowed to lie in the ground and perhaps late in the year, serve them for a cover crop. Thus treated, they push out in autumn, and in January or February abound in fine cabbage-sprouts, not much inferior to young cabbages. Sometimes this practice is applied to the earliest spring or summer crop in which case the sprout-cabbages come into use the following autumn.

3506. Cabbage-coleworts are gathered when the leaves are as broad as a man's hand. The largest are drawn up by the root, which is generally allowed to remain attached to those taken to public markets, as it retains the sap, and tends to preserve them succulent a longer period, than if they were wounded close to the succulent leaves.

3507. Preserving cabbages. Where this is thought necessary, the plants are laid down on their sides, and the stems covered with earth close to the head, the outer part of the more exposed side of which may be sometimes injured, but the inside remains sound.

3508. To save cabbage-seed. The raising of the seed of the different sorts of cabbage, Neill observes, affords employment to many persons in various parts of England. It is well known that no plants are more liable to be spoiled by cross breeds than the cabbage tribe, unless the plants of any particular variety, when in flower, be kept at a very considerable distance from any other; also, in flower, bees are extremely apt to carry the pollen of the one to the other, and produce confusion in the progeny. Market-gardeners, and many private individuals, raise seed for their own use. Some of the handsomest cabbages of the different sorts are dug up in autumn, and sunk in the ground to the head; early next summer a flower-stem appears, which is followed by abundance of seed. A few of the soundest and healthiest cabbage-stalks, furnished with sprouts, answer the same end. When the seed has been well ripened and dried, it will keep for six or eight years. It is mentioned by Bastien, that the seed-growers of Aubervilliers have learned by experience, that seed gathered from the middle flower-stem produces plants which will be fit for use a fortnight earlier than those from the seed of the lateral flower-stem: this may deserve the attention of the watchful gardener, and assist him in regulating his successive crops of the same kind of cabbage.
PRACTICE AND IN POOR DELICATE

The red or purple cabbage is similar in form to the white, but of a purple or brownish-red color.

The red cabbage is chiefly used for pickling; and the dwarf red variety, Nell observes, "certainly does make one of the most beautiful pickles that can be presented at table." Both the dwarf and large sorts are sometimes shredded down in winter, in salads, like red beet-root; and the Germans prepare sour kroust from all or any of the varieties.

There are three principal varieties of red cabbage, viz.

The large red, or red Dutch; with a large, firm, round head, usually cultivated in market-gardens.

The dwarf red; with a small, round, firm, delicate head, less common than the other.

The Aberdeen red; with an open leafy head, chiefly found in cottage gardens in the north of Scotland.

The propagation, sowing, and culture are in all respects the same as for the white cabbage; excepting that the heads are not used when imperfectly formed, or as coles; but the plants should, in all cases, be allowed to stand till they have formed close firm heads. Sow in August for a crop to stand the winter, and to come in at the close of next summer, and thence till the end of autumn. Sow early in spring for returns in the following winter and spring.

The Savoy is distinguished from the other close or hearted cabbages by the ruggedness of its leaves; and from the Brussels sprouts, by its cabbaging in large full heads. The Brussels sprouts is considered a subvariety.

The Savoy is in use as a table-vegetable from November till spring, unless destroyed by frost, in which case, it is succeeded by the borecoles or winter greens. These two classes of the cabbage tribe generally supply the table from November to May.

These are—

The green and The yellow Savoy; and of each of these are—

The oblong, and The conical, or sugar-loaf headed.

The green and The dwarf, and

The round

Estimate of sorts. The green Savoy is the least hardy, and must be used first. The London market is generally supplied with it through the month of November, and until the plants are injured by frost. The dwarf Savoy is harder than the preceding, bearing well the attack of the first winter frosts, by which the delicacy of its flavor is materially improved; and from its small size, it is better adapted to the tables of private families. Where the whole class is cultivated, this must be considered the second sort in succession. The best plants grow close to the ground, not exceeding a foot in height. The yellow Savoy, by its hardness, enables us to continue its use the longest in winter. It does not yield, any of the others in goodness, and by many persons it is preferred, being considered much sweeter. (Hort. Trans. vol. ii. p. 368.)

Propagation. The Savoy is always raised from seed, and for a seed-bed four feet and a half by eight feet, half an ounce of seed will be sufficient.

Soil and situation. This excellent answers best on a light rich soil: poor or exhausted ground should be manured according to the defects of it. Allot an open compartment in the full air, that the seedlings may be broad and strong, and not draw up weak and long stemmed, as they are liable to do in close situations, or narrow borders, under walls.

Sowing. A sufficient succession is obtained by three, or at most, four sowings, made from the last week of February till the second week in May; for planting out, from May till September. A small number of seed must be sown at the end of February, or the beginning of March, to plant out for early autumn Savoys, to cabbage in August or September. Sow a larger portion in the last fortnight of March for a first considerable autumn and winter crop. Nor omit to sow a full supply in the second or third week of April, for a main crop to be planted out in June, July, and the beginning of August, to attain a full cabbage growth late in autumn, and to stand partly over the winter. Furthermore, it would be eligible to make a moderate sowing at the beginning, or towards the middle of May, in order to plant out the seedlings in July, August, or September, for smaller heading, to come in towards the spring, and to stand longer before they run; or, some to use occasionally in winter, as Savoy coleworts.

Culture. The ground should have been previously trenched to a good depth. Four feet is a convenient width for the beds. Sow wide-cast; and rake in a quarter of an inch deep. As soon as the plants have two or three leaves, an inch or two in width, if they stand too crowded, thin the seed-beds, by drawing out the less regularły, and prick them into other beds four inches asunder. Should the weather be dry, water those left, as well as those removed. Permit both divisions to remain three, four, or five weeks, to gain a good stocky size for final transplanting. When the plants, both in seed-beds and those pricked out, are advanced, select two leaves, or three inches broad, or more, transplant them finally to open compartments of ground, which are to be covered, that they may cabbage with large full heads; planting them at different times as ground becomes vacant. Remove the most forward in May or June, for early autumn heading in August or September. But plant the principal crops in June or July, and from the beginning to the middle of August; taking all possible advantage of fine, calm, dry weather. In transplanting the plants, observe if any are clubbed or knotty at the root, and cut off the protuberances close. Plant in rows those removed in May, June, or July, two feet and a half, or not less than two feet asunder, by the same distance in the rows; others late planted in August and September, two feet by eighteen inches. In scarcity of vacant ground, some Savoys may be occasionally planted between wide rows of previous stand crops, such as beans, cauli-flowers, and early cabbage, that are sufficiently forward to be gathered off by the time the Savoys will want the entire ground. Before and after plantings made in dry weather, watering would be of essential service. As the plants are at the different successions of advance, keep them from weeds by occasional broad hoeing. At the same time, loosen the surface of the earth, and draw some about the stems of the plants; let this be done twice or often, to forward them in a free enlarging growth. They will gradually heart, fully cabbaging in September, October, November, December, &c. as they are the crops of the forward, or...
later sowings: they may be cut for use accordingly, and during the winter. The Savoys left standing will continue good till the middle or end of February, when, or in the course of March, they open and send up seed-stalks.

3321. To save seed. See Cabbage. (3508.)

3329. The *Brussels sprouts* produce an elongated stem, often four feet high, from the base of the leaves of which sprout out shoots which form small green heads like cabbages in miniature, each being from one to two inches in diameter, and the whole ranged spirally along the stem, the main leaves of which drop off early. The top of the plant resembles that of a Savoy planted late in the season; it is small, and with a green heart of little value. Van Mons says (*Hort. Trans.* vol. iii.), "If this vegetable be compared with any other which occupies as little space, lasts as long, and grows as well in situations generally considered unfavorable, such as between rows of potatoes, scarlet runners, or among young trees, it must be esteemed superior in utility to most others." Nicol considers it as deserving more general culture in Scotland; and Morgan (*Hort. Trans.* vol. ii.) says, it is an excellent sort of winter green for the table, but not sufficiently hardy to last through the winter in England.

3323. Use. The sprouts are used as winter greens; and at Brussels they are sometimes served at table with a sauce composed of vinegar, butter, and nutmeg, poured upon them hot after they have been boiled. The top, Van Mons says, is very delicate when dressed, and quite different in flavor from the sprouts.

3326. Cult. The plants are raised from seed, of which an ounce may be requisite for a seed-bed, four feet by ten feet. Van Mons, in the paper already referred to, says, "The seed is sown in spring under a frame, so as to bring the plants forward; they are then transplanted into an open border with a good aspect." By thus beginning early and sowing successively till late in the season, he says, "we contrive to supply ourselves, in Belgium, with this delicious vegetable, full ten months in the year; that is, from the end of July to the end of May." The plants need not be placed at more than eighteen inches each way, as the head does not spread wide, and the side leaves drop off. In this, as in every other respect, the culture is the same as that of the borecole.

3325. Gathering the crop. Morgan says, the sprouts must have some frost before gathered; but this Van Mons assures us is an erroneous opinion. In Belgium, the small cabbages are not esteemed if of more than half an inch in diameter. It is usual to cut off the top about ten or fifteen days before gathering from the stem. In spring, when the sprouts are disposed to run to flower, their growth is checked by taking up the plants, and laying them in the ground in any shaded spot.

3326. To save seed. Van Mons says, it is usual to save the seeds indiscriminately from plants which have or have not been rolled; but that he intends to save from the tops only, hoping thereby to improve the progeny. Whatever mode be adopted, the grand object is to place the plants where they will be in no danger of receiving the farina of any other of the brassica tribe.

3327. The *borecole* contains several subvarieties, the common characteristic of all which is an open head, sometimes large, of curled or wrinkled leaves, and a peculiar hardy constitution, which enables them to resist the winter, and remain green and fresh during the season. Morgan says, it is impossible to find a plant of more excellence for the table, or more easily cultivated than the common borecole. Sinclair recommends the Woburn perennial kale, which has been grown six years at Woburn Abbey. It shoots up yearly from the stool, like a true perennial plant, scarcely ever flowers, and is considered as producing more than thrice the produce of any other borecole, with a very great saving of manure and labor. It is considered by Sinclair as peculiarly adapted for farm and cottage gardens.

3328. Use. The crown or centre of the plant is cut off so as to include the leaves which do not exceed nine inches in length. It boils well, and is most tender, sweet, and delicate, provided it has been duly exposed to frost.

3329. Sub-varieties. These are—

1. The green borecole, Scotch kale, or Siberian borecole
2. The purple or brown kale
3. The German kale, German greens, or curles
4. The variegated borecole
5. The dwarf or dwarfed cabbage
6. The chou de Milan
7. The Egyptian kale, rash kale, or kohl kale
8. Ragged Jack

9. The Jerusalem kale
10. The Buda kale, Russian kale, Prussian kale, and by some called the Manchester kale
11. The palm-borecole, or chou-palmier
12. The thousand-head cabbage, or turnip-borecole, (B. o. var. *sabel-lica*, Dec.) chou-maure, Fr.
13. The Portuguese or large-ribbed borecole
14. The Woburn perennial kale, with finely cut leaves.

3350. Estimate of sorts. The three first sorts are the most valuable, and the most generally cultivated: the third sort is almost universally preferred in Britain. The seventh, eighth, and ninth sorts, being dwarf, stemless plants, resist black frosts, and come in for a late supply; the third, fourth, fifth, and tenth sorts are of common sorts; and the others are of little merit.

3351. Propagation of the first thirteen species. All the sorts are propagated by seed, which is sold by weight: and for a seed-bed four feet by ten, Abercrombie says, one ounce of seed is necessary. Sow in the last fortnight of March, in April, in the beginning of May, and in August. The first week in April for the principal crop of German kale; and the first week in August for the latest spring crop of Buda kale, and which will be ready to transplant in September.

3532. Subsequent culture. "When the plants have leaves one or two inches broad, take out some from the seed-bed, and prick into other open beds, six inches apart, giving water; in which let them have four or five weeks' growth. Then left in the seed-bed, as well as these, will all acquire proper strength for final transplanting in May, or thence till August. Taking the opportunity of rain, if possible, plant them in an open compartment, in rows two feet and a half square, for the first forward plantings in summer; the others two feet; allotting the whole similar distances in the rows. Give occasional water, if dry weather, till they have struck root. In their advancing growth, hoe the plants once or twice, to cut down rising weeds, and to draw earth about the bottom of the stems, to encourage their growth in the production of large full heads in proper season, September, October, &c." At the approach of winter, the stems should be blanch'd, and the heads gathered, for the hills round each plant will be of such a size and breadth as to cherish the roots of the dwarf varieties, and serve as a protection to the tall sorts in stormy weather.

3533. Gathering. "The heart is to be gathered of all the tall sorts, after which, with the exception of the German kale, and the chou de Milan, the stalks should be pulled up, and taken to the compost-heap or dunghill; but the terms of the two sorts excepted are to be left for the sake of their side shoots or sprouts. Of the dwarf sorts, the heart may either be cut off, for which the Buda kale and coleworts are well suited; or the leaves gathered when the plant begins to grow, which corresponds with the habits of the Egyptian and Jerusalem kale.

3534. Propagation of the Woburn kale is effected by cuttings of six or seven inches, which readily take root, and may be planted at once where they are finally to remain: the best season is March and April.

3535. Culture of the Woburn kale. "About the beginning of April, or as soon as winter greens are out of season, the stems are cut down near to the ground, within two buds of the roots, the soil is then slightly forked over, and afterwards kept clear of weeds by the hoe. This is all that is required." (Hort. Trans. v. 299.)

3536. Blanching the Buda or Portuguese kale. Wedgwood writes to the Horticultural Society, "I have been trying an experiment with Buda kale, which has answered completely; this is blanching it as you do sea-kale, by turning a pot over it, and letting it remain covered till it is quite blanched. When cut and dressed in that state it is excellent, and one advantage will be, that the same plant will furnish two cuttings, for the sprouts are more delicate than even the original heart of the plant. I used no dung to force it; but this might be applied with great advantage; and I think it would be an excellent substitute for sea-kale." (Hort. Trans. iv. 570.)

3537. To save seed. This can seldom be done of more than one or two sorts in the same garden, on account of the risk of promiscuous impregnation by bees, the wind, &c. As the seed, however, will keep for several years, good specimens of one or two sorts may be selected every year in rotation, and placed in spots distant from each other, in autumn, or early in spring. Trench the root and stem into the ground, at nearly double the distance at which they stood in the plantation. This will allow abundance of air to circulate round the blossoms and seed-pods. They will be ripe in August, when they may be gathered, and threshed out; and the seed, after being exposed to the dry air in the shade for a few days, put up in bags till wanted for use.

SUBSECTION. 6. Cauliflower — Brassica oleracea, var. etelatrus, L. and Dec. Chou-

fleur, Fr.; Blumenkohl, Ger.; and Cavoli fiori, Ital.

6358. The cauliflower is one of the most delicate and curious of the whole of the brassic tribe, the flower-buds forming a close, firm cluster or head, white and delicate, and for the sake of which the plant is cultivated.

3539. Use. "These heads or flowers being boiled, wrapped generally in a clean linen cloth, are served up as a most delicate vegetable dish. Cauliflower is a particular fa-

vorite in this country. 'Of all the flowers in the garden,' Dr. Johnson used to say, 'I like the cauliflower.' Its culture, however, had been little attended to till about the close of the 17th century; since that time it has been greatly improved, insomuch that cauliflowers may now fairly be claimed as peculiarly an English product. Till the time of the French Revolution, quantities of English cauliflower were regularly sent to Holland; and the Low Countries, and even France, depended on us for cauliflower-seed. Even now, English seed is preferred to any other." For the early supply of the London market, very great quantities of cauliflower are fostered under hand-glasses during winter and the first part of spring; and to behold some acres overspread with such glasses, gives a stranger a forcible idea of the riches and luxury of the metropolis. (Neill, in Ed. Encyc.)

3540. The sub-varieties in cultivation are —

Early, for the first early crops

Red cauliflower; having the stalks of the head of a reddish or purple color, &c.

Latter, or large, for principal early, and main crops

seemed more hardy than the others, and

good for an early crop.

3541. Propagation and soil. The cauliflower is raised from seed, to which half an ounce is sufficient for a seed-bed four feet and a half wide, by ten in length. The soil for the seed-bed may be light; but for final transplanting, it can hardly be too rich, the cauliflower, like the vine, being reputed a "rough feeder." Cleanings of streets, stables, cess-pools, &c. ought therefore to be liberally supplied during the growth of the plant, until very large heads are desired.

3542. Times of sowing. "The early and main superior crop, brought to fruit by the longest nursery attendance; the late summer succession crop, raised by the shortest course; and the Michælmas crop, obtained at the least expense; are sown respectively at three different seasons. The principal sowing is made about the end of the third week in August, or a day or two before or after the 21st, to raise plants to stand over the winter, under frames, hand-glasses, or half sheltered in warm borders, for the early and
main superior crops next summer. A secondary sowing in February or March, for succession and late

injury of the crop the summer in summer and autumn. A final sowing near the close of May, for ordinary
crops into the open weather." cauliflower. Early sown seeds will be ready to transplant till the
last week in August, and that if the seedlings are not transplanted till the middle or near the end of
November before the hard weather sets in, no sort of covering is necessary, nor any other protection than that
afforded by a wall having a south aspect. In such a border, and without any covering, young
cauliflower-plants have successfully stood a frost of a month's duration, and have kept them
and sounder plants for spring planting than such as have had additional shelter. The seedlings protected
and frames generally grow too gross in the stems, which become partly blackened; and the plants being
thus unhealthy, are not fit for planting out. Late raised seedlings, which spend the winter in the
open ground, as well as those protected by the table cases in the greenhouse, must be kept under the
shelter for a little while during the first freezing nights, at which time, if the frost should become
very severe, they certainly do not become quite in so early. Cauliflower-plants, it is probable, are often killed with too much
attention. Seedlings raised late in autumn seem to be very tenacious of life." (Caled. Hort. Misc. iii. 192)

543. Sowings to stand the winter. "Time of sowing and first culture. For the early and general crops next
summer, make a considerable sowing in August, about the eighteenth, and thence to the twenty-fourth
day of that month; or two different sowings between those times, at three or four days' interval, to
raise young plants to stand the winter under protection; some being planted out finally the same year
in October or November, under hand-glasses, and the others picked into frames and warm borders, for
planting out finally in the spring, into the open ground, to succeed the hand-glass fruit, or for the general
summer crop. Sow in a bed of rich, light, mellow earth. After sowing, give occasional light waterings in
dry weather, that the sowing is covered before the earth dries up, and then give a more constant supply
of water after the plants have become firmly established. Keep them close during hot weather,
an inch and a half broad, in September, prick them into intermediate beds, three or four inches apart;
watering, and occasionally shading from the mid-day sun, till they have taken root; to remain in such
beds till the middle of October till October.

544. Hand-glass division. "Then towards the close of October, transplant a quantity finally into rich
ground, which has been well dunged, under hand glasses, in rows three feet and a half or four feet
asunder (with interwoven alleys a foot wide), and three feet apart in the row. Set three or four
plants close to each other, with the dew-heads, or rich glasses containing each plant, in the
spring. Give a moderate watering at planting, and put on the glasses close till the plants take
root, discoverable in a week or ten days by their showing a renewed growth; then raise the glasses on
the warmest side, one or two inches in mild days, to admit free air to the plants. Continue the glasses all
weather, except when the earth is frozen hard. In mild south side, and early frosts occurs, or during
vicissitudes of the season, continue the glasses till the close of April or beginning of May; giving larger
admissions of free air as the warmer season of spring advances: and sometimes in fine mild weather,
admit a moderate warm shower of rain. Meanwhile, in March, if all or most of the plants under
the glasses are not sufficiently advanced, and the only one set out, in the glass, requiring transplan
ting the superabundant into the open garden, in a compartment of rich mellow earth, improved
with rotten dung digged in a spade deep; setting the plants two feet and a half asunder, and giving water.
In thinning the plants, be careful to take out those with black shanks; but do not take the trouble to try
and keep them. As they grow, plant them at about two feet from each other. At the same time, to assist the
several under hand glasses, draw a little earth at the stem of each. To these continue the glasses till the period
mentioned above, to forward them in full growth for the most early production; but as they expand in the

beads as for as possible, three or four inches high, to admit air freely, and to give a larger amount of free air as
the weather becomes milder; or, when the glasses are removed, and the earth is prepared and
ledge of earth round the bottom of each glass, both to raise the props higher, for an additional upward
space, and to contain water when occasionally given in dry weather. Towards the end of April, or the
beginning of May, in fine weather, remove them to the warm border, or handsome glasses in the open
field, and forward, but continue the aid of glass as long as practicable, to accelerate the plants into early heading
in May. Thus the most early crop will produce a supply of flower-heads for gathering in succession in May
and June."

543. Frame division. "The other plants of the same sowing, designed for wintering in frames, may, in
young growth, at the end of September, or beginning of October, be either pricked at once into the winter
beds, or be, at that time, removed into a preparatory bed in the open garden, to have a month's growth,
in order to be transplanted into the frame-beds at the end of October or beginning of November, in rows
crosswise the bed, four by three inches apart. Give a light watering, and put on the lights of the frames
close till the plants have taken root; then prop up the lights behind, two or three inches, or draw them off
occasionally to the back of the frame in mild, dry days, but keep on when very cold, and in rain, snow,
fruits, and always at night; and when the glass is full, close the frame. In dry, long, and mild winter,
small plants. But in all mild, dry weather, admit the air freely, as in mildness the hand glasses
Then in March or beginning of April, transplant the whole into the open garden, in rows two feet and a
half asunder; and they will come into full production in July and August.

546. "To this may be added, also, a frame filling of plants or hand-frames, that may, in October, either prick
some plants into a warm south border, close under the fence, three inches apart, to be protected in rigor
works, with mats, dry litter, or reed pannels; or you prick some in a bed arched over with hoops, to receive a covering of mats during cold nights, or heavy rain, snow, and frosts, in the day-time in winter. Give to full air in all moderate weather, till March or April; then fill to be transplanted finally as above."

5347. Drummond, of the Cork botanical garden, protects cauliflower-plants during winter by planting them
in excavations made in the common soil of the garden, and covered with frames, which, with long
and strong walls, are adjusted in the open weather whether or not days. Hort. vi. 356.

5348. Secondary sowing, or first spring-raised crop. "For late succession summer cauliflowers, to succeed the
summer crops, in the same season, may be sown in the middle of March; or, if necessary in December or
January, sowing in the spring, February, or beginning of March, in a moderate hot-bed, or, where that cannot be had, in
a warm border under a frame or hand-glass; and when the young plants have leaves an inch broad, prick
them into other beds of the same description, three inches apart, to gain strength by three or four weeks' growth,
in order to be planted out in the open garden, at the end of April or the beginning of May, when
their stalks may be transplanted;

Book 1. CAULIFLOWER. 613

R 3
The last and best sowing is for the late autumn and winter crop, commonly called the Michaelmas crop; to be made towards the twenty-fourth of May, in a bed of light earth. Prick out the young plants in June, to remain in the intermediate bed till about the middle of July, when they are transplanted two feet and a half saunder. Give occasional watering till they have taken good root. They will begin to produce heads in October, but the fruit will be of superior size in November and December, if temperate weather follow.

With respect to the culture of the different crops after being fixed in the ground, it is to hoe the ground occasionally, in order to cut down weeds, and as well to loosen the earth, and draw some round the stems of the plants. When the early crops are nearly advanced to full growth, in May and June, one or two good waterings to the roots will contribute to their producing large heads. In the dry weather of meridian summer, water those not in flower twice a week; and those in flower, every second day. As the flowers show themselves, turn down some of the larger leaves, to defend them from sun and rain, and to preserve them white and close, in perfection. (Abercrombie.)

The seed of early cauliflower is sown in a south border in the beginning of July, thins to 12 or 14 inches apart, and in June short heads produced from ten to thirty inches in height. The middle heads show themselves, turn down some of the larger leaves, to defend them from sun and rain, and to preserve them white and close, in perfection. (Abercrombie.)

For this purpose it is usual to pull up the plant entire, and hang it up in a shed or cellar, or to lay the plants in sand in cellars or sheds, covering the flower with the leaves, and being careful to remove every decayed part as it appears. The head or collar is not at hand for this purpose, a mode may be resorted to which has been adopted by Smith, and described by him in the Colcut. Hort. Mem., vol. i. p. 123, and which consists in burying the entire plant in a pit about eighteen inches deep, dug along the bottom of a wall. On a dry day he takes up the plant, and wrapping the leaves round the head of the flower, deposits them in the trench, the heads sloping downwards, and the roots extending upwards, so that the roots of the one layer cover the tops of another. Next, he covers up the whole closely with earth, sloping it from the wall, and beating it smooth with the back of the spade, so that rain may run off. In this way he preserves it in a good state from November to January. The best mode, however, of preserving cauliflower seed, is by raising the plants with balls, and trench-planting them in frames, or the borders of peach or grape houses not in action, taking care to keep the soil dry, and to remove decayed leaves; or, where frames are in sufficient quantity, to place a few over the plants as they stand in the compartment.

To save seed. "Mark and leave some of the prime plants of the thoroughly nursed early and main crops in May and June, when the flower-heads are in highest perfection; as those of late production will not ripen seed effectually. The stools will afford ripe seed in September; when be careful to watch the chaffinches, green-birds, &c. and to gather the branches as the seed upon them ripens. Lay them elevated from the ground, in some sunny, airy situation, to dry and harden to full maturity: after which let the seed be beaten and rubbed out, cleaned and sifted from the husky parts, spread on a cloth to dry the whole equally; and then put up for sowing the following year." (Abercrombie.)

Cauliflower-plants, when first planted out, are frequently infested with flies, or their larve, to attract which, it is not uncommon to sow a little radish-seed on the cauliflower ground a fortnight before transplanting; the flies preferring the tender leaves of the radish to those of the cauliflower, the latter are thus suffered to escape.

The few broccoli that were known in Miller's time are supposed to have proceeded from the cauliflower, which was originally imported from the Isle of Cyprus, about the middle of the 10th century. Miller mentions the white and purple broccoli as coming from Italy; and it is conjectured, that from these two sorts all the subsequent kinds have arisen, either by accidental or premeditated impregnations.

The same as the cauliflower.

Subvarieties. Neill observes, that "no culinary plant is so liable to sport as broccoli; so that new kinds, slightly different, are continually coming into notice or favor, and as speedily sinking into neglect. The common characteristic of broccoli, as distinguished from cauliflower, is color in the flower and leaves, and a comparatively hardy constitution to stand the winter. Maucher observes (Hort. Trans. vol. i. p. 118.), that as all plants of the brassica tribe become less alkaliescent, and more palatable in proportion as they are pale or white, so plants of broccoli, such as var. spring, var. pale, &c. are much finer and more suitable ones, if they turn out equally hardy. H. Ronalds, of Brentford, has given (Hort. Trans. vol. iii.) a Description of the different sorts of Broccoli, with an Account of the Method of cultivating them, from which we have all the data to compose this article. The sorts which follow are placed in the order in which they come in perfection to table.

Purple cape, or autumnal broccoli. This has a close, compact head, of a beautiful purple color; the leaves are nearly entire, erect, concave, lobed at bottom, and much waved, short, and regularly surrounding the head; the veins and midrib are stained with purple, which stain is a test of its being true; the head is exposed to the view in growing; in general it is not very large; as it enlarges, the projecting parts of the flower show a greenish-white, mixed with the purple color. When boiled, the whole flower becomes green. If the season is showery, and this variety is planted in good ground, it comes as large as cauliflower.

Culture of the purple broccoli. Sown about the middle of May, and beginning and end of June, it will produce in regular succession from August to December, or until frost destroys the heads. Sown in July, or even in early August, the winter is often too late, and the plants will be injured by the beginning of September, and the plants preserved in frames as cauliflowers, fine heads may be expected in the months of June and July. Thus, by good management, this kind may be in use during the greater part of the year; but it is not hardy enough to be depended on for the winter months. The plants grow from one foot to one foot and a half high, and should be placed about two feet apart in every direction.

Maher's mode of treating the purple broccoli is as follows: "Three crops are sown annually: the first between the 12th and 18th of April; a second between the 18th and 24th of May; the third between the 20th and 29th of August; these successive crops supply the family from September till the end of May. The seeds are scattered exceedingly thin, a border of very rich light earth. Not a weed is suffered to
appear, and when the young plants have grown to ten leaves, which is in about a month, they are finally planted out, at the distance of two feet every way, in a piece of sandy loam, which has been well prepared for them. They require, for the first few weeks, a large portion of very rich manure, which is then turned over to pick out every sort of grub, or insect deposited in it. The ground is kept constantly clean by hoeing whenever a seed-leaf of any weed springs up, and the loose surface is drawn together into a heap round the stem of each plant. The second crop is treated exactly as the first, but the weaker plants left in the seed-bed are removed to two or three feet distance from each other, but not so much longer as to gain more strength. They are then transplanted into pots of the size called sixteens, filled with very rich compost, placing them close to each other in the shade, and duly water the plants, till they begin to grow freely. After this, the pots are plunged in this manner about at two feet distance from each other every way, and protected at the general level, leaving a hollow or small plant, to remain in water given to them when necessary. By the time the pots are filled with roots, and that autumnal rains render watering unnecessary, the basins are filled by drawing the earth round each plant, at the same time pressing it firmly down, to prevent the wind from shaking them. In this manner the plants in pots sometimes show flowers too small, and to guard them from early frost, a leaf or two is broken down over them. On the approach of settled frost in December and January, all the pots are taken up and removed to a frame, pit, or shed, where they can be sheltered from the extreme severity of the winter, but have air when it is milder, and by this means they are subjected to the hardest winter that can be found, by experience, that it should be potted immediately from the seed-bed. If it is transplanted earlier, the head or flower is both less in size, and runs much sooner after it forms. For the same reason, I never pick out or transplant the general crops; and as the temperature of our climate does not suffer vegetation to go on briskly from October to March, by following this method, the heads of flower will remain a long time in a state of rest after they are formed, without bursting, and heads from six to seven inches diameter are the ordinary produce of our plants. The seeds of the third crop are sown in a frame, or under glass-houses, and about the third week in October, the plants become strong enough to remove, as in the two former crops."

5361. Green cape, or autumnal broccoli. This sort differs but little from the preceding, except in color and in the heads, as well as the plant, proving in general larger. The leaves are long and narrow, much like a bok choy, but are not curled, and, as the plants attain a considerable smoothness; the veins and mid-rib are green. The head, which has some resemblance to a cauliflower, is of a greenish-white color, and is usually somewhat covered by the leaves. These two sorts are very sportive, running much into each other, and have a strong tendency to degenerate, yet are quite distinct, and when they should be taken care of, the seeds from the plants which are perfectly true. This remark applies generally to all the sorts.

5362. Grange’s early cauliflower broccoli. If this sort is sown at three different times, from the beginning of May until the end of June, it will bear its heads in succession from Michaelmas to Christmas, if the weather be suitable. If attacked by mildew in the slaty earths, the long naked foot-stalks, are wider and shorter than those of the green cape, are lobed at bottom, but not much waved; the veins and mid-rib are whitish green; the head is large and quite white. It should be planted at about two feet apart.

5363. Close-headed winter broccoli. This is a new and good sort, apparently a seedling from the green cape, which it closely succeeds in coming into use. The plants are dwarf; leaves spreading, and moderately indented, they are numerous, much waved and large; the veins are white; the flower green. It is truly resembling the green Cape, and is as per of the same sort. 1870.

5364. Culture. The difficulty of this sort is, that it must not be seen to bear during the whole of the winter, if the weather is mild. A single plant, from seeds sown in May, Ronalds found to yield heads fit for use, through the months of November, December, January, and February. Plant from one foot to one and a half feet from each other, and two feet distance apart.

5365. Early purple broccoli. This is a very excellent kind, of a deep purple color; if the true sort, it is close-headed at first; afterwards it branches, but it is apt to come green, and too much branched, especially in rich ground. The plants are from two to three feet high, growing strong and tall; the leaves are much indented, of a purplish-green color, they spread out wide, but not long, though the stalks are so; the head is quite open from the leaves; small leaves are sometimes intermixed with the plant: produce sprouts of flowers from the alze of the plant.

5366. Culture. When sown in April, it begins to produce in November, and continues bearing the heads, which after the third year of several years; if sown in June, it produces abundance of sprouts in March and April. It should be planted three feet apart in rich ground.

5367. White broccoli. The heads of this sort are of a close texture, and of a pure white color. It grows to about three feet in height, with erect, concave, light-green, and nearly entire leaves.

5368. Culture. When sown in February, it begins to produce in November, and continues bearing the heads in March and April. It produces sprouts in March and April. It should be planted three feet apart in rich ground.

5369. Dwarf brown close-headed broccoli. From its resemblance, I take this to have sprung from the sulphur-colored broccoli, of which, however, it differs, by coming in earlier, as well as in the shape and color of its head; the leaves are also shorter and broader than those of the sulphur-colored; they are spreading, with concave mid-rib; they grow in the same name, and do not have the same height. Most of the crowns are green on their first appearance, but soon change to large, handsome, brown heads. 1830.

5370. Culture. Sown about the middle of April, it is in use through March and April. Two feet distance is sufficient for the plants, when put out.

5371. Tall large-headed purple broccoli. This sort produces large, tall, purple heads, at two and three feet in height.

5372. Culture. If sown towards the end of March, it will prove a useful kind in March and April. The plants will grow to three feet and a half high.

5373. Cream-colored, or Portsmouth broccoli. This is a very noble sort, excelling all the others in size. It is of a buff or cream color, and has a very compact firm head; its leaves are large and broad, with white veins; they spread out widely, but the small centre leaves cover the flower. A head, sent by Oblacere from the Swiss, and raised by me, and cultivated in the garden; the flower is of a slight green color, and does not cover the stem as well.

5374. Culture. Seeds sown in the middle of April will be in perfection during the following February, March, and April. It bears near the ground. The plants should be planted three feet and a half apart.

5375. Spring white, or cauliflower broccoli. This sort grows very robust, with large leaves, flat and narrow, with thick veins; the leaves encompass and compress the head, so as to render it generally invisible when fit to cut, which is a great preservative from the frosty mornings in the spring months.
PRACTICE as planted, it is of deep or a sect is water, which, transplant, the disease transplanting. The leaves are much undulated and indented, narrow and long, with a tinge of purple color in the stems. The seeds should be sown in April, and the plants must stand from one foot and a half to two feet apart.

3583. General observations on the culture of broccoli. All the sorts are raised from seed; and for a bed four feet in width by ten feet, Abercrombie says, one ounce of seed is sufficient.

3584. Seed-bed. Ronalds, in the paper above quoted, directs the seed-beds to be prepared of rich mould, well dug, and if dry, watered the evening before sowing. The seeds must be thinly sown, and the beds should be covered with mats or litter till the plants appear, the covering may then be removed, and the plants watered occasionally as the state of the weather requires; should that continue very dry, the best method is to transplant, when the plants are about two or three inches high, into other beds about four inches asunder. Being several times refreshed by sprinklings of water, they will, in a fortnight or three weeks, be sufficiently strong for a second remove. This mode offers some advantage in giving time to clear off any crops of peas, &c. thereby obtaining ground which could not otherwise be conveniently had at the first season of planting out. The four first sorts on the list, which I consider as congeners, should be only once transplanted, as the check their removal occasions is apt to produce the heads prematurely, which, in that case, will be small, and indifferent in quality. If the season is showery, it will be needful to cover the beds as soon as sown with netting, to keep off the birds, also to sprinkle the plants when they appear with lime-water, or to stew on them fresh-slacked lime, to destroy the slugs. In this case, when the plants are six or eight inches high, they may be planted at once at the distances recommended for each sort.

3585. Insects and diseases. In old gardens, infested, as is often the case, with an insect which in summer insinuates itself into the roots of all the brassica tribe, and causes a disease usually called the club, trenching the ground deep enough to bring up four or six inches of fresh undisturbed loam or earth, will probably bury the insects too deep for mischief, and provide fresh ground for the benefit of the plants. In gardens much exhausted by reiterated cropping, if this mode cannot be adopted, a good quantity of fresh loam from a common or field, dug in, would materially improve the broccoli, and be of lasting use to future crops. Broccoli, in general, succeeds best in a fresh loamy soil, where it comes, I think, more true in kind, and is harder, without dung; but if this situation cannot be had, deep digging, with plenty of manure, is the only remaining alternative to procure good crops. I believe soap-ashes, dug into the ground in considerable quantities, to be a good preservative from the club; and if the roots of the plants, just previously to planting, are dipped and stirred well about in mud of soap-ashes with water, its adherence will, in a great measure, preserve them from attack; perhaps a mixture of stronger ingredients, such as soot, sulphur-vivum, tobacco, &c. would be still better. (Hort. Trans. vol. iii.)

3586. Wood, a writer in the Caledonian Horticultural Memoirs, says he has paid a considerable degree of attention to the culture of broccoli, and has made considerable progress therein. He finds that manuring with a compound of sea-weed and horse-dung produced the largest and finest heads he had seen during a practice of fifty-four years.

3587. Culture without transplanting. M'Lecod grows cape broccoli in a very superior manner without transplanting. In the end of May, after having prepared the ground, he treats it firm, and by the assistance of three writers, some of his seeds lie, four feet apart, a foot in distance from each other in the row. When the seeds vegetate, he destroys all except the strongest, which are protected from the fly, by sprinkling a little soot over the ground; as the plants advance they are frequently flat-leeved until they bear their flowers; they are often earthed up, during their growth. A specimen of the broccoli thus grown was exhibited to the Horticultural Society; the head was compact and handsome, measuring two feet nine inches in circumference, and weighing, when divested of its leaves and stalk, three pounds; the largest of its leaves was upwards of two feet long. M'Lecod adopts the same modification of springing, of mulch flowers, of sowing, and almost all other vegetables, avoiding transplanting as much as possible. (Hort. Trans. vol. iv. 550.)

3588. Preserving broccoli during winter. Ronalds observes, that, though broccoli come larger and finer on the spot where they are planted, yet it is prudent to take up a part of the latter "sort in the beginning of November, disturbing the roots as little as possible, and lay them in slopeing, with their heads towards the north, only a few inches above the ground, and about eighteen inches asunder. By this means, the crown of the plant lying low, is soon covered and protected by the snow, which generally falls previously to long and severe frosts; the plant is also rendered tougher in fibre, and harder, by the check received in this last removal."

3589. Knight, having practised laying in his broccoli-plants in November in the usual way, found but small heads produced from them in the succeeding spring; till he tried trenching or laying them in the month of September, and "so low as that the centre of the stem at the top of each plant was level with the surface of the ground." The plants are watered, roots are properly emitted, and the earth drawn

5390. Nicot takes up the most forward crops of broccoli in the end of October, and lays them on their sides, so as the heads may not touch each other. In a dry soil and open situation, the plants will thus resist the severest winters.

5391. Gathering. In gathering broccoli, five or six inches of the stem are retained along with the head; and in dressing, the stalks are peeled before boiling. Some of the sorts produce sprouts from the sides of the stems, with small heads, that should be gathered when ready, and are very good when boiled.

3592. To save seed. Wood, already mentioned, selects the largest, best formed, and finest heads, taking particular care that no foliage appears on the surface of the heads; these he marks, and in April lays them in by the heels in a compound of cleanings of old ditches, tree-leaves, and dung. When the head begins to open or expand, he cuts out the centre, leaving only four or five of the outside shoots to come to seed. Lifting, he says, prevents them from producing proud seed, as it is called, or degenerating. The above method produces seed the most genuine of all the others he has tried. The sulphur broccoli he finds the most difficult to procure seed from. (Caled. Hort. Mem. vol. ii. p. 267.) Abercrombie says, broccoli-seeds degenerate in this country, and that the best seed is obtained from Italy.

SUBSECT. 8. Of the Insects which infest the Cabbage Tribe.

3593. The whole of the cabbage tribe are liable to the attacks of the larvae of the "Brassica oleracea," L. on their roots, and of the caterpillars of butterflies (fig. 464.) and moths (fig. 465.) on their leaves, as well as of aphides, or cabbage-lace, snails, and slugs. There is no remedy for the first, except that of taking up, cleaning, and transplanting in fresh soil, in a different part of the garden; and it is in general easier to plant afresh from the seedbed. With respect to caterpillars, snails, and slugs, they can only be gathered by hand, and the way to do this effectually is to begin as soon as they appear, employing women or children to look them over daily early in the morning. Poultry, and especially ducks and sea-gulls, are sometimes of use in keeping these and other insects under; a hen and chickens will devour caterpillars and aphides greedily, but are apt to scratch the soil afterwards, if not timely removed; turkey fowls are better. Nature has furnished a remarkable insect, which assists man in the destruction of the caterpillar, the "Ichneumon manifestator," L. (fig. 466.) "The insects of this genus," Samouelle observes, "lay their eggs in the bodies of caterpillars or pupae, which are there hatched; the larvae, have no feet; they are soft and cylindrical, and feed on the substance of the caterpillar, which never turns to a perfect insect, while the larva of the ichneumon spin themselves a silky web, and change into a pupa incompleta, and in a few days the fly appears." (Entomologist's Companion, 68.) Ante, 2661.
3594. Preventive device. "If in a patch of ground where cabbages are to be planted some hemp-seed be sown all round the edge, in the spring, the strong smell which that plant gives in vapor, will prevent the butterfly from infesting the cabbages. The Russian peasantry, in those provinces where hemp is cultivated, have their cabbages within those fields, by which they are free from caterpillars." (J. Busch, in Hort. Trans. vol. iv. 569.)

3595. The principal disease to which the cabbage is liable, is the club in the root. The cause is doubtful, but most probably it proceeds from the puncture of an insect in depositing its eggs. The part swells and becomes a tubercle as large as a gooseberry, and sometimes the size of a hen's egg. When it has attacked plants before transplantation, the root on which it appears should be cut off before planting; in the case of transplanted crops there is no remedy but taking up, cutting off, and re-transplanting. Some in planting apply ashes, lime, &c. at the roots, but nothing of this sort has been found of much advantage. In general, frequent transplanting (as prickling out twice or oftener before making the final plantation) is a palliative, as it promotes fibrous roots, and the club attacks chiefly those which are ramose.

Sect. II. Leguminous Plants.

3596. The leguminous esculent are of great antiquity as culinary vegetables; the British islands are supposed to be less favorable to them, than to most others, all the diadelphous plants of Linnæus, or leguminose of Jussieu, thriving best in a dry atmosphere, and comparatively arenaceous soil. These, it must be allowed, are more common in other countries than in ours. The space occupied by this tribe in the kitchen-garden, during the spring and summer months, is very considerable; probably amounting to an eighth part of the open compartments, and warm borders; but towards autumn, as the crops ripen, it is given up to be succeeded by other crops, chiefly of the cabbage and turnip tribes. These, independently of other circumstances, having fibrous or surface-roots, succeed well to the tap-roots of the bean and pea. In cottage gardens, the bean is very profitably grown among cabbages and potatoes; and the pea and kidneybean may occupy a space to be filled up in October with winter greens. We shall take them in the order of the pea, bean, and kidneybean.

3597. The pea is a hardy annual, a native of the south of Europe, and cultivated in this country from time immemorial. It was not very common, however, in Elizabeth's time, when, as Fuller informs us, peas were brought from Holland, and were "fit dainties for ladies, they came so far, and cost so dear." It is a climbing plant, with the legends, or pods, commonly produced in pairs, the seeds contained in which are the part of the plant used.

3598. The use of the pea is familiar in cookery. In one variety, called the sugar-pea (pois des courches, Fr. ?), the inner tough film of the pods is wanting; and such pods, when young, are frequently boiled with the seeds or peas within them, and eaten in the manner of kidneybeans. This variety is comparatively new, having been introduced about the middle of the 17th century.

3599. The varieties of the pea are numerous: the principal are——

Early Charlot : an excellent early sort nearly equal to the genuine frame
Early golden Charlot
Early Nichol's golden Charlot
Common Charlot
Early single-blossomed
Reading Hotspur; long pods
Dwarf marrowfat; large, long pods
Tall marrowfat; most large, long pods
Green marrowfat, Flemish
Knight's wrinkled, or marrow; a white-
blossomed, tall, luxuriant grower; the fruit of excellent flavor, cream-colored, and shreded when ripe and dried
Spanish moroito ; large
Prussian blue ; great bearer
Eng. ; large
White rouncival ; large, fine pods
Green rouncival; dull
Grey rouncival; ditzo
Tall sugar; large, crooked pods
Dwarf sugar

Crown, or rose; of tall, strong growth; producing its blossom and fruit in a
bunchy tuft at
Leediman's dwarf; a great bearer, but of small pods; good for a later crop, or as required for succession
Spanish dwarf; of low growth, small pod
Early frame; for forcing
Nanteuse, or earliest French pea.

3600. Estimate of sorts. "The varieties, besides differing in the color of the blossoms, height of the stalks, and mode of growth, are found to have many material differences in hardiness to stand the winter, time of coming in, and flavor of the fruit. The Charlots are not only very early, but great bearers, and excellent peas for the table; and are therefore equally well fitted for the early crop, and forward succession crops, and inferior to few even for the main summer crops. The frame-pea may, indeed, be raised without the assistance of heat for a forward crop; and, if a genuine sort, will fruit a few days sooner than the Charlot; but it grows lower, and bears scantily. The Hotspur is hardy and prolific, and makes returns nearly as early as the Charlot, and about a fortnight before the marrowfat. The sorts already specified, therefore, embrace the best for sowings made from the end of October till the middle of January, and for late crops raised between the middle of June and the beginning of August. The fine flavor of the marrowfat, for which it is valued, is from a dwarf marrowfat that may be sown in December and January, as mild weather may occur; but the time for sowing full crops of the larger kinds of peas, is from the beginning of February till the end of April. Knight's pea, one of the newest varieties, is very prolific, and retains its fine sweet flavor when full grown. The egg, the moratto, the Prussian blue, and the rouncivals, the large sugar, and the crown, are all very fine eating peas in young growth; and, like the marrowfat, may be sown freely, according to the demand, from the third week of February, till the close of April, and, in smaller crops, until the middle of June. For late crops, in addition to the early sorts already mentioned, the dwarf sugar, Leadman's dwarf, and Spanish dwarf, is very suitable. The Leadman's dwarf is a small delicious pea, a great bearer, and in high request at genteel tables; but as the fruit is long in coming,
in, it is not advisable to sow it after the third week in June; rather sow it in March, April, and May, and then it will not be later than the Charltons raised five weeks afterwards. The Charltons and Hotspur, may be sown in May, for late full crops; in June for a smaller supply: and in July, along with the frames for the last returns.

3901. Times of sowing. "Much that relates to this has been incidentally mentioned in the Estimate of sorts. To try for a crop as early as possible, sow, of the sort preferred as hardy and forward, a small portion on a sheltered south border, or other favorable situation, at the close of October, or rather in the course of November. December, with another sowing in December, has a long been made for the crop from a-sowing; and in the early and intermediate crops, to take the larger portion of the ground in December or January, if open temperate weather. To provide for main crops, make successive sowings of the suitable sorts from February till the end of May. It frequently proves, that the fruit from a sowing at the beginning of February, is not a week later than that from a crop raised in November; nay, the February crop may have stood as long as a month shorter, in forward weather, and of equal quality. From the middle of February make successive sowings every three weeks in the course of March, April, and May; or twice a-month in summer, when a continued succession is to be provided till the latest period. At the close of the sowing season, July and the first week of August, sow a reduced quantity of each; because the returns will depend on a fine mild autumn following, and whatever fruit is obtained will be small and scanty."

3902. Quantity of seed. Of the small early kinds, one pint will sow a row of twenty yards; for the larger sorts for main crops, the same measure will sow a row of thirty-three yards.

3903. Access to success. For early sorts, make the drills one inch and a half deep; and let parallel drills be two feet and a half, three, or four feet asunder. Peas that are to grow without sticks require the least room. For summer crops and large sorts, make the drills two inches deep, and four, five, or six feet asunder. As to the distances along the drill, distribute the peas according to their ten and the season: the frame, three in the space of an inch; the Charltons, Hotspur, and dwarf marrowfat, two in an inch; the Prussian blue and middle-sized sorts, three in two inches; the large marrow-fat and Knight's, a full inch apart; the moratto, rounceivals, and most larger sorts, an inch and a half apart; and the Pato- gian, an inch and a half.

3904. Soil and situation. "The soil should be moderately rich, and the deeper and stronger for the lofty growers. Peas are not assisted, but hurt, by unreduced dung recently turned in. A fresh sandy loam, or road-stuff, and a little decomposed vegetable matter, is the best manure. The soil for the early crops should be firm and even, but be ground in May, or by mixing it with a part of the previous year's com manure. For the larger sorts, the soil may be less well worked, but the situation becoming sandy will be most suitable. For early crops, put in from October till the end of January, let the situation be sheltered, and the aspect sunny. Before the end of December, every one or two rows should stand close under a south or south-eastern fence. In January, several parallel rows may be extended under a good aspect fence and if the weather is moderate, the fence. After the end of May, sow in an open situation. For the late crops, return again to a sheltered sunny border."

3905. Subsequent culture. "As the plants raise from an inch high to two or three inches, begin to draw earth to the stems, doing this when the ground is in a dry state; and earthing gradually higher as the stems ascend. At the same time, with the hoe loosen the ground between the young plants, and cut down rising weeds. Early crops should be protected during hard frosts by dry straw or other light litter, laid upon sticks or brushwood; but remove the covering as soon as the weather turns mild. If in April, May, and the course of summer, continued dry weather occurs, watering will be necessary, especially to the plants in blossom and swelling the fruit; and this trouble will be repaid in the produce. Rows partly cut off may be made up by transplanting. This is best done in March. In dry weather, water, and in hot days, shade, until the plants strike. All pea fruit better for sticking, and continue longer productive, especially the larger sorts. Stick the plants when six to twelve inches high, as soon as they begin to vine. Provide branchy sticks of such a height as the sort will require: for the frame and Leadman's dwarf, three feet high; for the Charlton and middle-sized, four or five feet; for the marrowfat and larger kinds, six or eight feet; for the round, and for Knight's marrow-fat, nine feet; and to form a row of sticks to each line of peas, on the most sunny side, east or south, that the attraction of the sun may incline the plants towards the sticks. Place about half the number on the opposite side, and let both rows stand rather wider at top than at the ground. Some gardeners stop the leading shoot of the most early sorts as it makes the pea plant mature."

3906. To forward an early crop. Sow or plant in lines from east to west, and stick a row of spruce-feather branches along the north side of every row, and sloping so as to bend over the plants, at one foot or eighteen inches from the ground. As the plants advance in height, vary the position of the branches, so that they do not remain over cold or rainy weather, but let the plants have the sun and the influence of the winter and spring sun. Some cover during nights and in severe weather, with two boards nailed together lengthwise, at right angles, which forms a very secure and easily managed covering, but excludes light. A better plan would be to gaze one of the sides, to be kept to the south, and to make good, to be called, which may then be retired one inch south after the other. (Hort. Trans. v. 381.) Had a single, or even two peas only been planted in each pot, and the plants turned out with their bulbs entire, the crop, no doubt, would have ripened still earlier.

For Spring Marrowfat, the best variety for this purpose is Knight's marrow-pea, which may be sown at intervals of ten days from the beginning to the end of June. "The ground is dug over in the usual way, and the spaces to be occupied by the future rows of peas are well soaked with water. The mould upon each side is then collected, so as to form ridges seven or eight inches above the previous level, and then covered with a thin layer of manure. The seeds are then planted four inches in the ridges, above the tops of the ridges. The plants grow vigorously, owing to the depth of soil and abundant moisture. If dry weather at any time set in, water is supplied profusely once a-week. In this way the plants continue grown and vigorous, resisting mildew, and yielding fruit till subdued by the heat. (Hort. Trans, &c., as hand- glasses are managed when over cauliflower; that is, to take them off in fine weather, or raise them constant or occasionally by brick-bats, or other props, as the weather and the state of the crop might require.

3907. Knight sowed peas in the open air, and peas in pots on the first day of March. In the last week of April, the peas in the open ground, and on the 29th of April, the transplanted plants were fifteen, and the others four inches high, and in June, the former ripened twelve weeks before the latter. (Hort. Trans. v. 381.) Had a single, or even two peas only been planted in each pot, and the plants turned out with their bulbs entire, the crop, no doubt, would have ripened still earlier.

For spring Marrow-fat, the best variety for this purpose is Knight's marrow-pea, which may be sown at intervals of ten days from the beginning to the end of June. "The ground is dug over in the usual way, and the spaces to be occupied by the future rows of peas are well soaked with water. The mould upon each side is then collected, so as to form ridges seven or eight inches above the previous level, and then covered with a thin layer of manure. The seeds are then planted four inches in the ridges, above the tops of the ridges. The plants grow vigorously, owing to the depth of soil and abundant moisture. If dry weather at any time set in, water is supplied profusely once a-week. In this way the plants continue grown and vigorous, resisting mildew, and yielding fruit till subdued by the heat. (Hort. Trans, &c., as hand- glasses are managed when over cauliflower; that is, to take them off in fine weather, or raise them constant or occasionally by brick-bats, or other props, as the weather and the state of the crop might require."

3908. Taking the crop. "The early crops are generally gathered in very young growth, often too young, when the pods are thin and the pease small, for the sake of presenting some at table as soon as possible. In the main crops there is no cause for precipitation: take them as they become pretty plump,
while the peas are yet green and tender. Leave some on to grow old; the young pods will then fill in greater perfection, and the plants will continue longer in bearing.

3510. To save seed. _"Either sow approved sorts in the spring, for plants, to stand wholly for seed, to have the pods ripe in full perfection; or occasionally leave some rows of any main crop; let all the early podded ripen, and gather the late formed only for the table, as the last gleanings of a crop seldom afford good full seed. For public supply extensive crops are commonly raised in fields. Let the seed attain full maturity, indicated by the pods changing brown, and the pea hardening; then be hooked up and prepared for threshing out in due time, cleaned, and housed._"

3511. For the method of forcing peas, see Chap. VII. Sect. XII.

3512. The garden-bean is an annual plant, rising from two to four feet high, with a thick angular stem, the leaves divided, and without tendrils; the flowers white, with a black spot in the middle of the wing; seed-pods thick, long, woolly within, and enclosing the large ovate flattened seeds, for the sake of which the plant is cultivated in gardens. It is a native of the cast, and particularly of Egypt, but has been known in this country from time immemorial, having, in all probability, been introduced by the Romans. _Crops of beans_,Neill observes, _"are very ornamental to the kitchen-garden, and render it a pleasant walk, the flowers having a fragrance not unlike those of the orange._"

3513. Use. The seeds are the only part used in cookery; and are either put in soups, or sent up in dishes apart.

3514. Varieties. The following are the principal sorts planted in British gardens: —

| Early small Mazagan | Broad Spanish |
| Early long-pod | White broad |
| Early small Lisbon | Large Kentish Windsor |
| Large long-pod | Large-Taylor’s Windsor |
| Large long-pod | Smallish mellow |

3515. Estimate of sorts. _"The Mazagan is one of the hardest and best flavoured of the small and early sorts. Mazagan is a Portuguese settlement on the coast of Africa, near the Straits of Gibraltar; and it is said that seeds brought from thence afford plants that are more early and more fruitful than those which spring from home-saved seed. The Lisbon is next, in point of earliness and fruitfulness; some, indeed, consider it, as a weed, which the Mazagan so commonly sown in Portugal is likewise an early variety, but it is planted chiefly for curiosity; it rises only six or eight inches high; the branches spread out like a fan, and the pods are produced in small clusters. The Sandwich bean has been long noted for its fruitfulness; the Toker and the broad Spanish are likewise great bearers. Of all the large kinds, the Mazagan is preferred both in the pot and the table. Very agreeable; when the plants are allowed room and time, they produce very large seeds, and in tolerable plenty, though they are not accounted liberal bearers. There are several sub-varieties, such as the broad Vandyke, Taylor’s Windsor, and the large Windsor beans, which rises about three feet high, and is a great bearer, the pods being long and narrow, and closely filled with oblong middle-sized seeds. This sort is now very much cultivated, and there are several sub-varieties of it, as the early, the large, and the sword long-pod. The white-blossomed bean is so called, because the black mark on the wing of the blossom is wanting. The seed is semi-transparent when young, but becomes clear and particularly bean flavor, and is on this account much esteemed; it is at the same time a copious bearer, and proper for a late crop. It may be mentioned, that Delaunay, in Le bon Jardineur, describes as excellent a new variety cultivated at Paris, which he calls the green bean from China; it is late, but very productive; and the plants grow even when the ground has been dried._"

3516. Times of sowing for early and successive crops. _"For the earliest crop, plant some Mazagans in October, November, or December, in a warm border, under an exposure to the full sun. Set them in rows two feet and a half to two and a half feet apart, or about an inch, and three or four inches apart in the rows; or some may also be sown in a single drill, under a south wall._" The most successful plan for nurturing a crop over the winter, is to sow the beans thickly together in a bed of light earth, under a warm aspect, for the intermediate object of protecting the infant plants the better from rigorous weather; and with the view of transplanting them at the approach of spring, or when the size of the plants (two or three inches in height) require it, into warm borders, at the distances at which the plants are to fruit. For this object, the width of a garden-frame is a convenient width for the bed, which should slope a little to the south. Sow two inches deep, either in drills, or by drawing off two-thirds the depth of the earth with a hoe or spade, scattering in the beans at the distance of about a square inch. At the approach of frost, protect the rising plants with a frame, hand-glasses, or the half-shelter of an awning of matting. In February or March, as soon as mild weather offers, transplant them into a warm south border, where they may come to full size under a large close, as three or four feet long-fence with the seed-bed with their full roots, and with as much mould as will adhere; pull off the old beans at bottom, and prune the end of the tap-root. Then plant them at the proper final distances, closing the earth rather high about the stems. Besides the benefit of previous protection, the fruiting of the beans is accelerated, and they are then ready to be transplanted to the furthest distance. If it were omitted to sow an early crop at the general season, a quantity may be sown thick in a moderate hot-bed, in January or February, or in large pots placed therein, or in a stove, to raise some plants quickly, for summer or winter forcing. The same instructions are given for the same green, and the young plants come up, give occasional protection in the severity of winter; and hoe up a little earth to the plants. Plants which can have no other shelter should be covered lightly with dry haulm or straw; but such a covering must be carefully removed as often as the weather turns mild. To succeed the above, plant more of the same sort, or some of the early long-pod or small Lisbon, in December or January, when mild weather, for larger supplies, in more open exposures. And in order to obtain either a more full succession, or a first general crop, plant some early and long-pods, and broad Spanish, at the end of March or April, and in the same style, in some other compartment of good mild compost. Some of the larger sword long-pod, Sandwich, and Toker beans, may also be planted in fuller crops, in February, March, and April. These long-pods, broad Spanish; all to be assigned under full exposure, in the main compartments. The Windsor ranks first in regard to flavor; but proves, on common soils, not so plentiful a bearer as the other late sorts. Plant also full succession crops, in March and April, and smaller portions in May and June, for late pro-
KIDNEYBEAN.

duction, especially the long-pod, broad Spanish, and Toker; also any of the early sorts, which are more successful in late planting, than the larger broad varieties. The white-blossomed bean, though the same species, is inferior in growing and the crops, and is less resistant to plant disease, than the larger varieties. A success of early varieties of the kidney bean, from March till June and July; being a great bearer, and a tender and sweet eating bean, if gathered young. Any of the other sorts named in the above list may also be planted occasionally, to increase the variety. For sowing in June and July, the small or early kinds again become the most popular, as their constitution fits them for standing late as well as early. Thus regular supplies may be provided for in succession, from June till September."

518. Quantity of seed. For early crops, one pint of seed will be requisite for every eighty feet of row, and forCELER Chicory, rather than every sixty feet of row; and for late crops, nearly the same as the early. For the main crops, the quantity cultivated in proportion to that for early or late crops, is generally treble or quadruple, as to the extent of ground: but a less quantity of seed is requisite for the same space.

519. Method of sowing. "Plant all the sorts in rows, two feet and a half apart, for the smaller, or very early, or very late kinds; and three feet for the larger: the smaller beans two inches deep, and three inches distant in the row; the larger three inches deep, and four inches distant in the row."

520. Transplanting. Specially marked transplants him early beans, especially, and consomers that this plant may be transplanted as cabbage, or any other vegetable. It is a practice with him to plant beans alternately with potatoes in the same row; the rows three feet apart, and the potatoes eighteen inches apart in the row, so that the beans are nine inches from the potatoes. The beans are transplanted, by which means they have the start and advantage of the potatoes and weeds, and as they come in early, may be gathered before they can possibly incommode or injure the potatoes."

521. Manual process. "The work of sowing is most generally effected by a disk, having a thick blunt end, to make a wide aperture for each bean, to admit it clean to the bottom, without any narrow hollow part below: strike the earth fully and regularly into the holes, over the inserted beans. Or the planting may be performed occasionally in drills drawn with a hoe the proper depth and distance as above; place the beans at intervals along the bottom of each drill, and earth them over evenly; which method, though suitable to any kinds, may be more particularly adopted in sowing the early and other small sorts."

522. Soaking seed in summer. "In planting late crops in June and July, if the weather be dry, it is either possible to cause the beans a previous soaking for several hours in soft water; or, if they are to be sown in drills, water the drills beforehand, then directly put in the beans, and earth them so that while the ground remains moist."

523. Subsequent culture. "As the plants come up, and advance from two to four or six inches high, hoe them clean, or at each row, cutting down all weeds. Repeat the hoeing as future weeds arise, both to keep the ground about the plants clean, and to loosen the earth to encourage their growth. In earthing up, great care must be taken that the earth do not fall on the centre of the plant so as to bury it; for this occasions it to rot or fail. After earthing up, stir between the rows with a three-pronged fork. As the different crops come into full blossom, pinch or cut off the tops, in order to promote their fruiting sooner, in a more plentiful production of well filled pods."

524. For forward an early crop, see this article under Pea. (3006.)

525. To produce a late crop as an expedient sometimes resorted to produce a late crop. A compartment of beans is fixed on; and when the flowers appear, the plants are entirely cut over, a few inches from the surface of the ground. New stems spring from the stools, and these produce a very late crop of beans."

526. For table use, gather only such as are tender, the seeds decreasing in delicacy after they attain about half the size which they should possess at maturity. When they become black-eyed, they are tough, and strong tasted, and much inferior for eating.

527. To save seed. "Either plant some of the approved sorts, in February or March, wholly for that purpose; or leave some rows of the different crops ungathered, in preference to the gleanings of gathered crops. The pods will ripen in August, becoming brown and dry, and the beans dry and hard: then pulling up the stalks, place them in the sun, to harden the seed thoroughly, after which thresh out each sort separately." (Abercrombic.)

528. To force the bean, see Chap. VII. Sect. XII.

529. The common dwarf kidneybean, the haricot of the French, and erroneously termed French bean, is the P. vulgaris, L. (Lob. Tc. 2. p. 59.) It is a tender annual, a native of India; and introduced in 1597, or earlier. Flowers from June to September. The species called the runner is the P. multiflorus, Willld. (Schl. Hen. 2. 7. 199. a.) a half hardy annual, and a native of South America, introduced in 1633. It is rather more tender than the other; produces flowers from July to September. The stem of both species is more or less twining, though little of this propensity is shown in the dwarfish kinds. The leaves are ternate, on long foot-stalks; the flowers on axillary racemes; the corolla generally white, sometimes yellow, red, or purple. The pods are oblong, swollying slightly over the seeds, which are generally kidney-shaped, smooth, and shining, when ripe, varying in color according to the variety, and either white, black, blue, red, or spotted. The fruit of both sorts may be had in perfection from the open garden, by successive crops from June to October. Speecly suggests (Practical Hints on Domestic Economy, p. 15.), that the culture of the kidneybean might become an object of national or field culture in this country, and be particularly useful in times of scarcity; "more especially, as on good land it will flourish and grow luxuriantly, even in a dry parching season; in which respect it differs from most other culinary vegetables." It is an article of field-culture in most warm countries, especially France and America.

530. Use. The unripe pods are chiefly used in Britain as a legume, for which they
are in great estimation throughout the year; being produced by forcing when they cannot be grown in the natural ground. They are also used as a pickle. On the continent, the ripe seeds are much used in cookery; forming what are called haricots, of different kinds, and entering into some sorts of soups. In the end of the season, when frost is expected, the haulm of the kidneybean crop is gathered and dried like that of the pea in this country, and the ripe beans afterwards threshed out, and preserved for use through the winter.

3633. Constitution and habits. Both the above classes of kidneybeans, dwarfs, and runners, are tender in their nature, unable to grow freely in the open ground before April or May; the seed being liable to rot in the ground from the effects of wet, if planted before the beginning of the former month, even in a dry soil. The plants are also affected by sharp cold, and make but little progress till settled warm weather. However, when sown a month or more after that period till the beginning of August, they succeed well, making liberal returns of fruit from June or July till October. The dwarfs require no support; but the runners, ascending eight or ten feet high or more, require tall sticks or poles to climb upon, or lines suspended from a contiguous building or fence. They produce abundant length of pods. The scarlet runner bears notice, that the runner should be inclined to the right, or in a direction contrary to the apparent diurnal course of the sun: this aberration from the common habits of plants has been accounted for by the native climate of the scarlet runner will be found to lie south of the equator, and that the plant, although removed to the northern hemisphere, is still obedient to the course originally assigned to it, turning in a direction which in its native climate, would be towards the sun. (Abercrombie.)

3634. Estimate of sorts. The dwarfs bear sowing a little sooner, and make returns quicker than the runners. They are, besides, more convenient to cultivate on a large scale; and the smaller pods which they produce bear better by many. A certain deficiency of flavor is observable in the larger supply from the dwarf species. The early yellow, early black, and early red-speckled, are among the hardest and most forward; the early white comes in a few days later, but is of superior flavor. The Canterbury, Battersea, black-speckled, brown-speckled, striped, and tawny, are plentiful harvesters for sale; the scarlet, dwarf, although, depend on the Canterbury and Battersea for small crops; but the others just named are also profitable sorts, and acceptable to the consumer. The dwarf kidneybean continues to produce young pods in abundance, and in perfection only about three weeks or a month. The Dutch runner, with a proper supply of fruit, has the same qualities as the dwarfs. The scarlet runner ranks first for its prolific property and long continuance in fruit; the pods are thick, fleshy, tender, and good, if gathered while moderately young. The Dutch variety is equally well adapted for a principal crop. The Dutch runner grows as luxuriantly as hops, and is also a great beater, in fine long pods, but not so lasting as the scarlet. As to the scarlet runner kinds, the Battersea and Battersea white dwarfs, of the ordinary species, are those most in use; but the Battersea and Battersea white dwarfs; casually shooting into runners: they bear, in tolerable abundance, slender nectar pods, which are very good and tender eating; though not so eligible for a principal crop of runners as the scarlet.

3635. Quantity of seed. Half a pint will sow a row eighty feet in length, the beans being placed from two a half to three inches apart.

3636. Soil. The soil for both species should be light and mellow, inclining to a dry sand for the early varieties, and clay loam for the late sorts in summer crops.

3637. Separate culture of dwarfs. About the beginning of April, if the weather be temperate, fair, and settled, make the first sowing, or in a dry south border, or other sheltered compartment with a good aspect, or sow in a single row close under a south fence; beginning with a small proportion of the most hardy early sorts that may be had. It is for the most part best to sow in a pot in the close and in the pot; if the sowings in case the former should fail. You may sow for a larger crop about the middle, or twentieth of April. For the early crops, make the drills two feet asunder. The common depth is an inch and a half for the smaller-sized beans. Drop the beans in each row at this season pretty close together, as many may fail; from one to two inches apart. Cover them in evenly the full depth of the drill. For the main crops, sow in July once or two and make a moderate sowing at the beginning of August for a late and last crop. In the drought of high summer, it is advisable to accelerate the germination of the seed, by laying it in damp mould, till it begins to sprout, or by soaking it in soft water for six or seven hours previous to sowing. Place by watering it by watering; May should be favored in situation, or the time of their bearing will be much shortened by the decline of the season. From this course of sowings, a regular succession of young green pods will be produced from June and July till October. As the plants of the different sorts advance in growth, occasionally hoe and stir the soil about the days when the runners are almost all even, to fully settle the plants as they rise to height, which will strengthen and forward them considerably. When advanced to full bearing, it is advisable to gather the pods in moderately young or medium growth.

3638. The scarlet kidneybeans may be sown in a small portion, towards the end of April, if tolerably warm dry weather; but as these beans are rather milder than the dwarf sorts, more liable to rot in the ground by wet and cold, especially the scarlets, the beginning or middle of May will be time enough to sow a considerable crop; and you may sow a full crop about the beginning of June. All of which, whether scarlet or white runner beans, the scarlet as runners are eligible for a secondary crop. The first crops should have the assistance of a south wall. Intermediate crops may be sown in any open compartment, or against any fence not looking north. The latest sown will continue bearing the longer under a good aspect and shelter. In sowing, draw drills about an inch and a half, or half, or when the rows are sown in the same place, about the same distance, draw parallel rows, and place the drills on the true as well as on the side of a walk; and have the support of a slight trellis of laths and lines; or they might be arched over with similar materials, to form a shady walk or bower. In a cold wet season, or when requisite to have a few plants more forward than the general crop, some scarlets may be sown in April, either in a slight hot-bed, or in pots, under frames or hand glasses, to raise and forward the plants till two or three inches high: then, at the end of May, transplant
them into the open garden. As the plants come up, and advance from three to six inches in growth, hoe some earth to the stems, cutting down all weeds. When they begin to send forth runners, place suitable supports to each row; and conduct the tendrils to the sticks or lines, turning them in a contrary direction to the sun. The ascending plants will soon come into flower, podding at the joints in long succession. They are so prolific that the returns from three sowings, in May, June, and July, will last from July to October.

3639. Taking the crop. Gather the pods, both from dwarfs and runners, while they are young, fleshy, brittle, and tender; for then they are in highest perfection for the table; and the plants will bear more fully, and last longer in fruit, under a course of clean gathering, not leaving any superabundant pods to grow old.

3640. To save seed. Either sow a portion for that object, or leave rows wholly ungathered of the main crops, or preserve a sufficiency of good pods promiscuously. The beans saved should be the first-fruits of a crop sown at a period which allows the entire course of growth into the finest part of summer. Let them hang on the stalks till they ripen fully in August and September; then let the hauum be pulled up, and placed in the sun, to dry and harden the seed, which should be afterwards cleared out of the husks, bagged up, and housed.

3641. Forwarding an early crop. The kidneybean is often partially forced in hot-houses or frames, with a view to its fruition in the open garden; and supplies of green pods are also kept up throughout the winter and spring months, by forcing in hot-houses and pits; for the details of both practices, see Ch. VII. Sect. X.

3642. Insects. The pea, bean, and kidneybean are liable to the attacks of various insects, especially the aphides in dry seasons. The Bruchus Pisi (fig. 468) is particularly destructive to the pea, and its larva (a) is often found in the ripe pod. In gardens, the only mode of keeping them under, is to cut off the part infested, and remove it with the insects attached. When early crops are newly sown or planted, mice will burrow for and eat the seed, and when it begins to penetrate the soil, it is attacked by snails and slugs, and sometimes by birds. The usual means of defeating the attacks of these and other enemies, must always be early resorted to by the gardener.

Sect. III. Esculent Roots.

3643. The esculent-rooted culinary plants delightful in a light, rather sandy, deep, and well stirred soil. It must be dry at bottom; but a moist atmosphere and moderate temperature are greatly favorable to the growth of almost the whole of the plants we have included in this section. Hence the excellence of the potatoe crop in Ireland, and the size to which turnips, carrots, parsnips, &c. attain in Britain and Holland, compared to what they do in France and Germany. The space occupied in the kitchen-garden by this class of vegetables is considerable; but as it is regulated in some degree by the quantity of the more common roots grown in the farm for culinary use, it is less subject to estimation. In most gardens, however, the esculent roots taken together may occupy as much space as the legumes. In cottage gardens, they may be considered as occupying one half of the whole, to be in part succeeded by winter greens.

3644. The potatoe is a perennial plant, well known for the tubers produced by its roots. The stem rises generally from two to three feet in height, with long and weak branches, furnished with leaves interruptedly pinnate. The flowers are white or tinged with purple. The fruit is a berry of the size of a plum, green at first, but black when ripe, and containing many small, flat, roundish, white seeds. It is supposed to be a native of South America, but Humboldt is very doubtful if that can be proved: he admits, however, that it is naturalised there in some districts.

3645. Sabine and Lambert consider it as satisfactorily proved, that it is to be found both in elevated places in the tropical regions, and in the more temperate districts of the western coasts of South America. (Hort. Trans. v. 250.; Jour. R. Inst. x. 25.) Some tubers, said to be of the wild potatoe, have been received by the Horticultural Society, and grown by them; they differ so little from those of the cultivated potatoe, that Sabine conjectures, "that the original cultivators of this vegetable did not exercise either much art or patience in the cultivation of their garden-potatoes." (Hort. Trans. v. 257.)

3646. Sir Joseph Banks (Hort. Trans. i. 8.) considers that the potatoe was first brought into Europe from the mountainous parts of South America, in the neighborhood of Quito, where they were called papas, to Spain, in the early part of the sixteenth century. From Spain, where they were called batatas, they appear to have found their way first to Italy, where they received the same name with the truffle, taratoyfi. The potatoe was received by Clusius, at Vienna, in 1598, from the governor of Mons, in Hainault, who had procured it the year before from one of the attendants of the Pope's legate, under the name of taratoyfi, and learned from him, that it was then in use in Italy. In Germany it received the name of cartoffel, and spread rapidly even in Clusius's time. To England the potatoe found its way by a different route, being brought from Virginia by the colonists sent out by Sir Walter Raleigh in 1584, and who returned in July 1586, and "probably," according to Sir Joseph Banks, "brought with them the potatoe." Thomas Herriot, in a report on the country, published in De Bry's Collection of Voyages (vol. i. p. 17.), describes a plant called openawk, with "roots as large as a walnut, and others much larger; they grow in damp soil, many hanging together, as if fixed on ropes; they are good food, either boiled or roasted."

3647. Gerrard, in his Herbal, published in 1597, gives a figure of the potatoe, under
the name of the potato of Virginia, whence, he says, he received the roots; and this appellation it appears to have retained, in order to distinguish it from the batatas, or sweet potato (Convolvulus batatas), till the year 1640, if not longer. "The sweet potato," Sir Joseph Banks observes, "was used in England as a delicacy long before the introduction of our potatoes: it was imported in considerable quantities from Spain and the Canaries, and was supposed to possess the power of restoring decayed vigor. The kissing comfits of Falstaff, and other confections of similar imaginary qualities, with which our ancestors were duped, were principally made of these and of cririgo roots."

3648. Gough, in his edition of Camden's Britannia, says, that the potato was first planted by Sir Walter Raleigh on his estate of Youghall, near Cork, and that it was "cherished and cultivated for food" in that country before its value was known in England; for, though they were soon carried over from Ireland into Lancashire, Gerrard, who had this plant in his garden in 1597, under the name of Batata Virginiana, recommends the roots to be eaten as a delicate dish, not as common food. Parkinson mentions, that the tubers were sometimes roasted, and steeped in sack and sugar, or baked with marron and spices, and even preserved and candied by the comfort-makers.

3649. The Royal Society, in 1663, took some measures for encouraging the cultivation of potatoes, with the view of preventing famine. Still, however, although their utility as an article of food was better known, no high character was bestowed on them. In books of gardening, published towards the end of the seventeenth century, a hundred years after their introduction, they are spoken of rather slightly. "They are much used in Ireland and America at present," says one author, "and may be propagated with advantage to poor people." "I do not bear that it hath been yet essayed," are the words of another, "whether they may not be propagated in great quantities, for food for swine or other cattle." Even the enlightened Evelyn seems to have entertained a prejudice against them: "Plant potatoes," he says, writing in 1699, "in your worst ground. Take them up in November for winter spending; there will enough remain for a stock, though ever so exactly gathered." The famous nurserymen, London and Wise, did not consider the potato as worthy of notice in their Complete Gardener, published in 1719; and Bradley, who, about the same time, wrote so extensively on horticultural subjects, speaks of them as inferior to skirrets and radishes.

3650. The use of potatoes, however, gradually spread, as their excellent qualities became better understood. But it was near the end of the eighteenth century before they were generally known over the country: since that time they have been most extensively cultivated. In 1796, it was found, that in the county of Essex alone, about 1700 acres were planted with potatoes for the supply of the London market. This must form, no doubt, the principal supply; but many fields of potatoes are to be seen in the other counties bordering on the capital, and many ship-loads are annually imported from a distance. In every county in England, it is now more or less an object of field-culture. The cultivation of potatoes in gardens in Scotland was very little understood till about the year 1740; and it was not practised in fields till about twenty years after that period. It is stated in the General Report of Scotland (vol. ii. p. 111.), as a well ascertained fact, that in the year 1725-6, the few potato-plants then existing in gardens about Edinburgh, were left in the same spot of ground from year to year, as recommended by Evelyn; a few tubers were perhaps removed for use in the autumn, and the parent-plants were then well covered with litter to save them from the winter's frost. Since the middle of the eighteenth century, the cultivation of potatoes has made rapid progress in that country; so that they are now to be seen in almost every cottage garden. The potato is now considered as the most useful esculent that is cultivated; and who, Neill asks, "could, a priori, have expected to find the most useful plant among the natural family of the Lirideae, L., several of which are deleterious, and all of which are forbidding in their aspect."

3651. Use. The tubers of the potato, from having no peculiarity of taste, and consisting chiefly of starch, approach nearer to the nature of the flower, or farina of grain, than any vegetable root production; and for this reason it is the most universally liked, and can be used longer in constant succession by the same individual without becoming unpalatable, than any other vegetable, the seeds of the grasses excepted. "So generally is it relished, and so nutritious is it accounted," Neill observes, "that on many tables it now appears almost every day in the year. It is commonly eaten plainly boiled, and in this way it is excellent. When potatoes have been long kept, or in the spring months, the best parts of each tuber are selected, and mashed before going to table. Potatoes are also baked, roasted, and fried. With the flour of potatoes, puddings are made nearly equal in flavor to those of millet; with a moderate proportion of wheat-flour, bread of excellent quality may be formed of it; and potato starch, independently of its use in the laundry, is considered an equally delicate food as sago or arrow-root." As starch and sugar are so nearly the same, that the former is easily converted into the latter, hence the potato yields a powerful spirit by distillation, and a strong wine by the fermentive process.

3652. Varieties. These are very numerous, not only from the facility of procuring new
sorts by raising from seed; but because any variety cultivated for a few years in the same soil and situation, as in the same garden or farm, acquires a peculiarity of character or habit, which distinguishes it from the same variety in a different situation and character. The varieties in general cultivation may be distinguished in regard to precocity, tardity, form, size, color, and quality.

3654. No blossoms are produced by any of the above sorts: they are roundish in form, small-sized, white, and not of the best quality.

3655. Tardity. The latest sorts are —

<table>
<thead>
<tr>
<th>The round purple</th>
<th>The oblong purple</th>
<th>The small purple</th>
</tr>
</thead>
<tbody>
<tr>
<td>The oblong purple</td>
<td>The red purple</td>
<td>The white purple</td>
</tr>
<tr>
<td>The oblong white</td>
<td>The yellow purple</td>
<td>The Irish red</td>
</tr>
<tr>
<td>The red navel</td>
<td>The Irish red</td>
<td>The white</td>
</tr>
<tr>
<td>The crimson</td>
<td>The pink-eyed</td>
<td>The black skin</td>
</tr>
</tbody>
</table>

3656. No blossoms are produced by any of the above sorts: they are roundish in form, small-sized, white, and not of the best quality.

3657. Of the round, the most esteemed are —

<table>
<thead>
<tr>
<th>The champion</th>
<th>Late and early varieties</th>
<th>The oxblood</th>
<th>Very large, and of a peculiar flavor</th>
</tr>
</thead>
<tbody>
<tr>
<td>The American red</td>
<td>The long and not thick</td>
<td>The Irish red, or pink</td>
<td>The oblong and entirely red, with hollow eyes</td>
</tr>
<tr>
<td>The bright red, blood-red, or apple-potato</td>
<td>Orate, with small full eyes, much grown in Cheshire and Lancashire, meaty and agreeably flavored</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

3658. The oxblood are —

<table>
<thead>
<tr>
<th>The red navel</th>
<th>Often confounded with the red kidney</th>
</tr>
</thead>
<tbody>
<tr>
<td>The oblong red</td>
<td>Varied with white</td>

</tr>
<tr>
<td>The bright red, blood-red, or apple-potato</td>
<td>Orate, with small full eyes, much grown in Cheshire and Lancashire, meaty and agreeably flavored</td>
</tr>
</tbody>
</table>

3659. The kidney-shaped are —

<table>
<thead>
<tr>
<th>The common white kidney</th>
<th>Of a peculiar flavor esteemed by many</th>
</tr>
</thead>
<tbody>
<tr>
<td>The red kidney</td>
<td>reckoned somewhat more hardy</td>
</tr>
</tbody>
</table>

3660. In size, the early sorts are the least, and the oxnoble and late champions the largest.

3661. In color, the early sorts are in general white, the oblong sorts red, and the latest sorts purple.

3662. In quality, potatoes are either watery, as the very early sorts; waxy, as the American and Irish reds; or mealy, as the ash-leaved early, the champion, the kidney, &c.

3663. The following list is recommended by the principal London seedsmen at the present time:

For forcing in frames, or for the first crop in the open garden.

| Fox's seedling | Early manesty | Early male | Broughton dwarf |

For general cultivation in the open garden or field.

| Early kidney | Good flavor, and very early, keeps well | Norvych; early, prolific | Early show; good early sort for general use |

For mace crops, arranged in the order of their ripening.

<table>
<thead>
<tr>
<th>Early champion</th>
<th>Very generally cultivated</th>
<th>Broad-fruit, originated about 1700, propagated, prolific, and mealy</th>
</tr>
</thead>
<tbody>
<tr>
<td>Red rose kidney</td>
<td>Lancashire pink-eye, good</td>
<td>Black skin, mealy, white, and good</td>
</tr>
<tr>
<td>Large kidney</td>
<td>Purple; very mealy, productive, and keeps well</td>
<td>Red apple; mealy, keeps the longest of any</td>
</tr>
</tbody>
</table>

3664. In general, every town and district has its peculiar and favorite varieties, early as well as late, so that, excepting as to the best early kinds, and the best for a general crop in all soils, any list, however extended, could be of little use. Dr. Hunter, in his Geographical Essays, has supposed the duration of a variety to be fourteen years; and Knight (Hort. Trans. vol. i.) concurs with him in opinion. There are some excellent sorts of party-colored potatoes in Scotland, which degenerate when removed from one district to another; and most of the Scotch and Irish varieties degenerate in England. The best mode, therefore, to order potatoes for seed is to give a general description of the size, color, form, and quality wanted, and whether for an early or late crop.

3665. Propagation. The potatoe may be propagated from seed, cuttings or layers of the green shoots, sprouts from the eyes of the tubers, or portions of the tubers containing a bud or eye. The object of the first method, is to procure new or improved varieties; of the second, little more than curiosity, or to multiply as quickly as possible a rare sort; and of the third, to save the tubers for food. The method by which portions of the tubers is the best, and that almost universally practised for the general purposes, both of field and garden and the object of the first method, is to procure new or improved varieties; of the second, little more than curiosity, or to multiply as quickly as possible a rare sort; and of the third, to save the tubers for food. The method by which portions of the tubers is the best, and that almost universally practised for the general purposes, both of field and garden and the object of the first method, is to procure new or improved varieties; of the second, little more than curiosity, or to multiply as quickly as possible a rare sort; and of the third, to save the tubers for food. The method by which portions of the tubers is the best, and that almost universally practised for the general purposes, both of field and garden and the object of the first method, is to procure new or improved varieties; of the second, little more than curiosity, or to multiply as quickly as possible a rare sort; and of the third, to save the tubers for food. The method by which portions of the tubers is the best, and that almost universally practised for the general purposes, both of field and garden and the object of the first method, is to procure new or improved varieties; of the second, little more than curiosity, or to multiply as quickly as possible a rare sort; and of the third, to save the tubers for food. The method by which portions of the tubers is the best, and that almost universally practised for the general purposes, both of field and garden and the object of the first method, is to procure new or improved varieties; of the second, little more than curiosity, or to multiply as quickly as possible a rare sort; and of the third, to save the tubers for food. The method by which portions of the tubers is the best, and that almost universally practised for the general purposes, both of field and garden
in the ground, I raised the mould in a heap round the bases of them, and in contact with the stakes: on their south sides I planted the potatoes from which I wished to obtain seeds. When the young plants were about four inches high, they were secured to the stakes with shreds and nails, and the mould was then washed away, by a strong current of water, from the bases of their stems, so that the fibrous roots only of the plant were left in the soil. This, however, was the case with the various roots, which give existence, and subsequently convey nutriment to the tuberous roots; and as the runners spring from the stems only of the plants, which are, in the mode of culture I have described, placed wholly out of the soil, the formation of tuberous roots is easily prevented; and whenever this is done, no result will almost ever be secured. In considering that the above facts, which are more fully explained in the *Philosophical Transactions* for 1806, were sufficient to prove, that the same fluid or sap gives existence alike to the tuber, and the blossom, and seedling, and potato, or a plant of any other nature, the production of tubers, or an increased expenditure of the riches of the soil, must necessarily take place, succeeded in producing varieties of sufficiently luxuriant growth, and large produce for general culture which never produced blossoms. (*Hort. Trans.*, vol. I, 1806.)

575. *Methods of formation of shoots from the tubers.* In default of genuine early sorts; or, to save the tubers for use in seasons of scarcity, the sprouts which are generally found on store-potatoes in spring, and picked off and thrown away as useless, will, when carefully planted in loose well prepared soil, yield a crop; and this crop may be a little sooner produced than one produced by the ordinary methods of planting, for which the buds are not advanced. Almost every thing, however, depends on the fine tilth, and good state of the soil.

575. *By cutting or layers, or suckers.* Make cuttings of the young stalks or branches, of five or six inches in length, in May or June; attending to the general directions for forming cuttings. Choose, if possible, showery weather; or strike them under a hand-glass, or in a half empty pot covered with a pane of glass, and striking cucumber-cuttings.

575. *In June or July, when the potato stalks are advanced one or two feet long, choose such plants as stand somewhat detached, and lay down the shoots on the ground with or without cutting, in the common mode of layering. Cover them with earth about three inches, leaving the points of the shoots exposed. These shoots will emit roots at every leaf, and produce full-grown potatoes the same year, attaining perfection in autumn.*

576. *Suckers.* Remove in June, off-set sucker shoots, with a few roots to each; plant them carefully, and they will produce a late crop like the latter.

576. *By cutting or layers from the stalks, or suckers.* Make cuttings of the young stalks or branches. In default of genuine early sorts; or, to save the tubers for use in seasons of scarcity, the sprouts which are generally found on store-potatoes in spring, and picked off and thrown away as useless, will, when carefully planted in loose well prepared soil, yield a crop; and this crop may be a little sooner produced than one produced by the ordinary methods of planting, for which the buds are not advanced. Almost every thing, however, depends on the fine tilth, and good state of the soil.

576. *By cutting or layers, or suckers.* In default of genuine early sorts; or, to save the tubers for use in seasons of scarcity, the sprouts which are generally found on store-potatoes in spring, and picked off and thrown away as useless, will, when carefully planted in loose well prepared soil, yield a crop; and this crop may be a little sooner produced than one produced by the ordinary methods of planting, for which the buds are not advanced. Almost every thing, however, depends on the fine tilth, and good state of the soil.

576. *Size of the sets.* The plants that have found for that a late crop small sets may be used, because the plants set of late varieties always acquire a considerable age before they begin to generate tubers; but for an early crop the largest tubers are to be had. If these sets have formed a tuber, or tubers, but not only uniformly large, but also such as readily recover when injured by frost: for being fed by a copious reservoir beneath the soil, a reproduction of vigorous stems and foliage soon takes place, when those first produced are destroyed by frost, or other cause. He adds, *when the planter is anxious to obtain a crop within the least possible time, let the position in which the tubers are placed to vegetate by no means a point of indifferen
cer; for these being shoots or branches, which have grown thick instead of elongating, retain the dis
disposition of branches to propel their sap to their leading buds, or points most distant from the stems of the plants, of which they once formed parts. If the tubers be placed with their leading buds upwards, a few very strong and very early shoots will spring from them; but if their position be reversed, many weaker and later shoots will be produced; and not only the earliness, but the quality of the produce, in size, will be much increased.*

576. *Quantity of sets.* In respect to proportioning the quantity of sets to the space to be planted, Abercrombie directs, *For a plot of the early and secondary crops, eight feet wide by sixteen in length; planted in rows fifteen inches asunder by nine inches in the row, a quarter of a peck of roots or cuttings. For medium and large crops, a third part, in length, planted in rows two feet distant by twelve inches in the row, half a peck of roots or cuttings will be required.*

576. *Soil and manure.* The best soil for the potato is a light, fresh, unmixed loam, where they can be grown without manure. Here they have always the best flavor. In a wet soil, they grow sickly, and produce watery tubers, infected with worms and other vermin. To a poor soil, dung must be applied; litter dung will produce the earliest and largest crop; but meadow dung, rotten leaves, or vegetable earth, will least affect the flavor of the tubers.

576. *Season for planting.* The *last fortnight of March, and first fortnight of April, is the most proper time for planting the main crops; a little earlier or later, as the spring may be forward or late, the ground dry or wet. Occasional plantings may be made in May, or even the beginning of June. (Aber
crombie.)*

576. *Methods of planting.* The sets of whatever kind, or the plants forwarded in pots, to be turned out with a little soil, and placed at a distance for potating; for producing an early crop in the open air, should always be inserted in regular rows; the object of which is to admit as little as possible of air between the plants, and of distant plants. The rows may be fifteen inches apart for the small early sorts; and for the larger, twenty inches or two feet, according to the poorness or richness of the soil. In the lines traced, make holes for the sets at eight, twelve, or fifteen inches' distance, letting their depth not be less than three, nor exceed five inches.

576. *Planting on a level surface will answer on a light soil.* In small gardens, the planting may be performed in large dibbles with a dibble or bar set upright at the end. For planting considerable crops, a strong larger dibble or bar is to be obtained. A dibble or bar of over a yard long, is used, with a cross handle of two feet in width, with a digging scroll or blade, with iron, and having a short cross iron shoulder about four or five inches from the bottom, as a guide to make the holes of an equal depth; one person striking the holes, and a boy directly dropping a set into each hole. Strike the dibble or bar with a dibble, hoe, or rake, either to each row is planted, or when the whole planting is finished. Sometimes the process is to open a small hole with the spade, and to drop in a set, which set is covered in by the opening of the next hole.

576. *Planting on the land.* The planting ought to be on raised beds with alleys, or in drills on the crown of parallel ridges. The beds may either be raised by previous digging, throwing on good earth, or terracing the desired height, or in the different method described below. To plant in drills, trace them at the medium distance above specified: form them to the proper depth with a narrow spade or large hoe; in these place the sets a foot or fifteen inches apart, and earth over. To avoid the incommodities of
low wet sandy ground, whether it be arable or grass land, or a cultivated garden, potatoes are planted in raised beds four feet wide, with alleys half that width between them. Buckets are thus raised, and without digging the surface, lay some long loose litter upon the intended beds. Upon this litter place the sets about a foot apart; and upon the sets apply more litter, equally distributed over the whole: then digging the alleys, turn the earth thereof upon the beds five or six inches deep; or, if grass, turn the sward downward, leveling the beds, and then the plants will produce a fine crop of tubers.

3890. Subsequent culture. "From the March or April planting, the stems generally rise fully in May. After the plants have appeared, give an effectual hoeing on dry days, cutting up all the weeds, and stir the ground about the rising stalks of the plants. When advanced from six to twelve inches high, hoe up some car to the bottom of the stems, to strengthen their growth, and promote the increase below: continue occasional hoeing to eradicate weeds, till the plants cover the ground, but when little further care will be required. Permit the stalks to run in full growth, and by no means cut down, as is sometimes practised; the lea the being organs for transmitting the beneficial influence of the sun and air to the roots, which is most necessary to the free and perfect growth of the tubers." (Abercrombic.)

3891. Pinching off the blossoms. It is now generally admitted, that a certain advantage, in point of produce, is obtained by pinching off the blossoms as they appear on the plants. The fact has been repeatedly proved, in a great number of instances, who imagined that the time was wasted in removing the blossoms, since in weight to the tubers of each plant, or considerably above a ton per acre. (Hort. Trans. vol. i. 190.)

3892. Taking the crop. "Clusters of roots in the early planted crop will sometimes by June or July be advanced to a state, when a still small portion should be taken up at a time; they are not wanted for immediate use, as they will not keep good above a day or two. In August and September, however, they will be grown to a tolerably good size, and may be taken up in larger supplies, though not in quantities for keeping a length of time. Permit the main winter crops to continue in growth till towards the end of October or beginning of November, when the stalks will begin to decay — an indication that the potatoes are fully grown: then wholly dig them up, and house for winter and spring. Let them then be taken up, before any severe frost sets in; having, for large crops, a proper potato-fork of three or four short flat times, fixed on a spade-handle. Cut down the haulm close, and clear off forward: then fork up the potatoes, turning them clean out of the ground, large and small; and collect every forking into baskets."

3893. Housing and preserving the crop. Abercrombic recommends "housing potatoes in a close, dry, subterranean situation, and thus to preserve them; as they are not covered so as to escape the autumnal "frost." There are to be looked over occasionally, and any that decay picked out. In spring, when they begin to shoot, turn them over, and break off the sprouts or shoots from each tuber, perfectly close, in order to retard their future shooting as much as possible. Potatoes so stored, will continue good all the winter, if they are kept in a dry, dark, cool place, till May and June.

3894. Prying (as it is called in some places) is a good method of preserving potatoes in winter. They are piled on the surface of the ground, in a ridged form, of a width and length at pleasure, according to the quantity, but commonly about five or six feet wide. This is done by digging a spit of earth, and laying it round the edge, a foot wide (if turf the better), filling the space up with straw, and then laying on a course of potatoes, dig earth from the outside, and lay upon the first earth. Put straw a few inches along the inside edge, then put in more potatoes, and so on, keeping a good coat of straw all the way up between the potatoes and the mound, which should be about six inches thick all over; beat it close together, and the form it lies in, with the trench all round, will preserve the potatoes dry; and the sharpest frost will hardly affect them; in a severe time of which, the whole may be covered thickly with straw. In the spring, look over the stock, and break off the shoots of those designed for the table, and repeat this business to preserve the potatoes the longer good.

3895. Curl disease. The disease called curl, has in many places proved extremely troublesome and injurious. It has given rise to much discussion, and to detail all the various opinions would be a useless task. It may, however, be remarked, that the experiments of Dickson (Caled. Hort. Mem. i. 55.) show, that one cause is the vegetable powers in the tuber planted, having been exhausted by over-ripening. That excellent horticulturist observed, in 1808 and 1809, that cuts taken from the waxy, wet, or least ripened end of a long flat potatoe, that is, the end nearest the roots, produced healthy plants; while those from the dry and best ripened end, farthest from the roots, either did not vegetate at all, or produced curled plants. This view is supported by the observations of a very good practical gardener, Daniel Crichton, at Minto, who, from many years’ experience, found (Id. p. 440.) that tubers preserved as much as possible in the wet and immature state, and not exposed to the air, were not subject to curl. And Knight (Hort. Trans. 1814.) has clearly shown the beneficial results of using, as seed-stock, potatoes which have grown late, or been imperfectly ripened in the preceding year. Dickson lays down some rules, attention to which, he thinks, would prevent the many disappointments occasioned by the curl. He recommends, 1. The procuring of a sound healthy seed-stock of tubers for planting from a high part of the country, where the tubers are never over-ripened: 2. The planting of such potatoes as are intended to supply seed-stock for the ensuing season, at least a fortnight later than those planted for a crop, and to take them up whenever the stems become of a yellow-green color, at which time the cuticle of the tubers may be easily rubbed off between the finger and thumb: 3. The preventing those plants that are destined to yield seed-stock for the ensuing year, from producing flowers or berries, by cutting off the flower-buds; an operation easily performed by children, at a trifling expense. Shirreff (Caled. Hort. Mem. vol. i. p. 60., and in the Farmer’s Magazine) controverts Dickson’s opinion, and accounts for the curl disease as the effects of old age, on the hypothesis that plants like animals will not live beyond certain periods, &c.

The essay is ingenious, but totally speculative. Young, who has paid much attention to the subject, has brought forward a variety of facts to show that the "curl on the young stem arising weakly arises chiefly from the two causes mentioned by Dickson and Crichton, over-ripe tubers, or the employment of seed-stock that have been improperly kept during winter, that is, kept exposed to the light and air instead of being covered with earth or sand, or straw, so as to preserve their juices." (Caled. Hort. Mem. iii. 278.) The same view, it may be remarked, had occurred to Dr. Hunter. A S s 2
fact ascertained by Knight deserves to be particularly noticed: it is this; that by planting late in the season, perhaps in June, or even in July, an exhausted good variety may in a great measure be restored; that is, the tubers resulting from the late planting, when again planted at the ordinary season, produce the kind in its pristine vigor, and of its former size.

3686. Crichton, who has made a variety of experiments on the effects of exposure to the air in hampers and open floors, and on exclusion of the air by covering with earth (Caled. Mem. vol. i. 440.), concludes, " That the curl in the potato may often be occasioned by the way the potatoes are treated that are intended for seed. I have observed, that wherever the seed-stock is carefully pitted, and not exposed to the air in the spring, the crop has seldom any curl; but where the seed-stock is put into barns and out-houses for months together, such crop seldom escapes turning out, in a great measure, curled; and if but few curl the first year, if they are planted again, it is more than probable the half of them will curl next season."

3687. For forcing potatoes, see Ch. VII. Sect. XI.

SUBSEC. 2. Jerusalem Artichoke. — Helianthus tuberosus, L. (Jac. Vind. 2. t. 161.)

3688. The Jerusalem artichoke is a hardy perennial, a native of Brazil, and introduced in 1617. It has the habit of a common sun-flower, but grows much taller, often rising ten or twelve feet high. The season of its flowering is September and October; but though its roots endure our hardest winters, the plant seldom flowers with us, and it never ripens its seed. The roots are creeping, and are furnished with many red tubers, clustered together, perhaps from thirty to fifty to a plant. Before potatoes were known, this plant was much esteemed. The epithet Jerusalem is a mere corruption of the Italian word Girasole (from girare, to turn, and sol), or sun-flower; the name Artichoke is bestowed from the resemblance in flavor which the tubers have to the bottoms of artichokes.

3689. Use. The roots are esteemed a wholesome, nutritious food, and are eaten boiled, mashed with butter, or baked in pies, and have an excellent flavor. Planted in rows, from east to west, the upright herb of the plant affords a salutary shade to such culinary vegetables as require it, in the midsummer months, as lettuce, turnips, strawberries, &c.

3690. Propagation. It is raised by planting, either some small offset tubers of the main roots, or middling-sized roots cut into pieces for sets, which is more eligible. Preserve one or two full eyes to each cutting.

3691. Quantity of sets. For a row 120 feet in length, the sets being inserted two feet apart, half a peck, or sixty roots, will be sufficient. (Abercrombie.)

3692. Culture. It will grow in any spare ordinary part of the garden; but to obtain fine large roots, give it an open compartment of pretty good mellow ground. The season for planting is February, March, or beginning of April. Having dug the compartment, plant them, either by dibble, in rows two feet and a half asunder, about eighteen inches in the lines, and three or four inches deep; or, in drills by a hoe, the same depth and distance. The plants will come up in April and May. In their advancing growth, hoe and cut down all weeds, drawing a little earth to the bottom of the stems. The root will multiply into a progeny of tubers, in a cluster, in each plant, increasing in size till September and October: you may then cut away the stems, and dig up the produce as wanting. Or, in November, when they are wholly done growing, it will be proper to take up a quantity, and lay in dry sand under cover, to be ready as wanting, in frosty weather, when the others are frozen up in the ground, or affected by the frost. As the roots of this plant are very prolific, the smallest piece of a tuber will grow. In taking up the produce, you should therefore clear all out as well as possible; as any remaining part will come up the following year disorderly, and pester the ground; and would thus continue rising for many years, but not eligible to cultivate for a good crop. Therefore, to answer a demand, make a fresh plantation every year. (Abercrombie.)

3693. The turnip is a biennial plant, growing in a wild state in some parts of England; but better known as an inhabitant of the garden and the farm. In its wild state, the root-leaves are large, of a deep-green color, very rough, jagged, and gashed; in the second season it sends up a flower-stalk, with leaves embracing the stem, smooth, glaucous, oblong, and pointed.

3694. Use. The use of the root, boiled and mashed as a dish, in broths, soups, and stews, or entire, is familiar over all Europe. The top-shoots, from such as have stood the winter, are gathered whilst tender, and dressed as spring greens or spinach. The seed is also sometimes sown as small salading. " The navet, or French turnip, is considered a distinct species, and is the B. Napus, L. and B. N. var. B. esculenta, Dec., or edible rape. It is a different plant from the navet of Decandolle, which he calls B. campestris, var. imperi- brassica." Of the true navet or French turnip cultivated in England, Dickson observes (Hort. Trans. vol. i.), "that it enriches all the foreign soups. Stewed in gravy, it forms a most excellent dish, and being white, and of the shape of a carrot, when mixed alternately with those roots upon a dish, it is very ornamental. In France, as well as in Germany, few great dinners are served up, without it in one shape or other." In using it, there is no necessity to cut away the outer skin or rind, in which, indeed, the flavor
chiefly resides; scraping it will be quite sufficient. Justice, that it is neither fit to be eaten boiled alone nor raw; but that two or three of them in seasoning will give a higher flavor than a dozen of turnips. (British Gardener's Directory, p. 159.)

6395. Varieties. Those in general cultivation are the

![Image](image_url) turnip.

**Early white Dutch**

- Early stone
- Common round white
- Large round white
- Yellow Dutch
- Aberdeen yellow
- Madeirardens; an excellent and beautiful root

**Green-topped large round white; skin of the crown green**

**Early large white**

**Turned; large oblong**

**French (B. napus, var. secalina), Navet de Monre, Fr.** small oblong

**Swedish (B. campestris, var. napo-brassica), Navet de Soerle, Fr.** large round, and a very finely planted root. Sow for field-culture than in gardens for the table.

6396. Estimate of sorts. The first three sorts are the fittest for early, first succession, and main summer crops for the table. The early white Dutch is proper both for the most early and first succession crops, as is also the early stone. The common round white is highly eligible for the main crop; and the large round white is remarkably fit to use down to corn with which it should be sown; it will do well for the late summer and autumn crop. In large grounds, portions of the large white green-topped, and the large white red-topped, may be sown for autumn and winter; but the surest plant for winter consumption is the yellow Dutch; although constituted to stand intense frost unhurt, it has a fine flavor, and is very nutritious. If sown in late March, or April, it will be cutting early in June; and for many years has answered a particular demand. The French, or navet, is of excellent flavor. It was anciently used throughout the whole of Europe, and was more cultivated in this country a century ago than it is now. It is still in high repute in France, Germany, and Holland. It is grown in the sandy fields round Berlin, and also near Altona, from whence it is sometimes imported to the London market. Before the war, the queen of Geo. III. had regular supplies sent to England from Mecklenburgh. The Swedish, for its large size and hardy nature, is extensively cultivated in fields for cattle: it is also occasionally raised in gardens for the table. The turnip grows well under Dutch.

6397. Seed estimate. For a bed-four feet and a half by twenty-four, the plants to remain and be thinned to seven inches’ distance, half an ounce.

6398. Time of sowing. This root can be obtained most part of the year, by sowing every month in spring and summer. If sown in the first fortnight of March, or the first days of April, for early turnips in May and June; but, as these soon fly up to seed the same season, adopt a larger early sowing about the middle of April. The first main sowing should follow at the beginning, or towards the end of May, for autumn, and June, and in July, for winter; sow the main crops in June and July, to provide the main supplies of autumn and winter turnips. Make a final smaller sowing in the second or third week of August, for late young crops, or to stand for the close of winter and opening of spring; the turnips of this sowing continue longer than those of the previous sowings before they run in the spring. As the crops standing over winter shoot up to seed-stalks in February, March, or April, the root becomes hard, stringy, and unfit for the table. Make the sowings a day or two before or after the prescribed times for the opportunity of showery weather, or, if, done at a dry time, give a gentle watering.

6399. Nature and situation. The turnip grows best in a light moderately rich soil, broken fine by good tillage. Sod or gravel, with a mixture of loam, produces the sweetest-flavored roots. In heavy excessively rich land, the plant sometimes appears to flourish as well; but it will be found to have a rank taste, and to be not so nourishing as those raised on exhausted soils. The turnip seed is to be selected and matured properly to suit the defect of the staple earth. Dung, when requisite, should have been laid on the preceding autumn; for when fresh, it affords a nidor for the turnip-fly. Let the early crop have a warm aspect, and the lightest dry soil. Sow the crops raised after the first of May in the most open situations.

6300. Process in sowing, and precautions against the fly. Let the ground be well broken by regular digging, and neatly levelled to receive the seed. Procure bright well-dried seed. At a season when the turnip-fly is not apprehended, the seed may be put into the ground without any preparation, either alone or mixed with a little sand, but in the hot weather of summer, it is advisable to use some cheap and effectual preventive of the fly. It appears from a trial of Knight, at the suggestion of Sir Humphrey Davy, that lime mixed with urine, and mixed with a treacle quantity of soil, if sprinkled in with the seed at the time of sowing, will prevent from the root the attack of this pernicious insect; but this article cannot be conveniently applied unless the sowing be in drills. A yet simpler remedy, found by May, to be perfectly successful, is, to steep the seed in sulphur-water, putting an ounce of sulphur to a pint of water, which will be sufficient for soaking about three pounds of seed. (Abercrombie.)

6301. Mixture of roots. The turnips of the same sort, particularly the late, may be mixed together in the seed, and be either broadcast or sown in drills; but it is better to sow each sort by itself, so that the fly corresponding with the same sort may be destroyed; and if the seeds be sown where the root can be done; the fly in its budding state having fed on other herbage, and disappeared before the turnip comes into leaf.

6302. Mincing equal parts of old seed with new, and then dividing the mixture, and sowing one half of it twenty-four hours in water, has often been tried with effect, and especially by farmers. By this means, four different times of vegetation are procured, and consequently, of course, seven crops of seed is frequently mixed with that of the turnip, and the fly preferring the former, the latter is allowed to escape.

6303. Nell’s says, “One of the easiest remedies, is to sow thick, and thus ensure a sufficiency of plants both to the crop and the fly. But if the crow’s be killed the fly will increase greatly; by the use of a fly made of sheep’s wool that can be done (in the fly in its budding state having fed on other herbage, and disappeared before the turnip comes into leaf.

6304. Abercrombie directs to “sow broadcast, allowing half an ounce of seed for every 100 square feet, unless some particular purpose will be answered by drilling. In the former method, scatter the seed regularly and thinly; in dry weather, trend or roll it in lightly and evenly; but after heavy showers, merely beat it gently down; rake in fine. Let drills be an inch deep, and twelve or fifteen inches asunder. In the hot weather, the root is greatly injurious; wait for rain, or water the field, for the fermentation caused by copious rain and heat gives an extraordinary quick vegetation to the seed, which in a few days will be in the rough leaf, and out of all danger from the fly. This insect is weakened or killed by drenching showers, and does no injury to the turnip when much rain falls. It is desirable in the following finishing with the twelfth of August, to over-sow with grass, to prevent the growth of Asparagus, and also to check the fly, and with corn, to prevent the growth of the leafy grasses. (Col. Hort. Mem., vol. I.)

6305. Reparation of a destroyed sowing. When a crop is destroyed by the fly, the necessary reparation is immediately to dig or stir the ground, and make another sowing; watering soon, and occasionally afterwards, unless rain falls.

6306. Successful culture. “As soon as the plants have rough leaves about an inch broad, ho and thin them to six or eight square inches’ distance, cutting up all weeds. As the turnips increase in the root, a part may be drawn young by progressive thinning, so as to leave those designed to reach a full size ultimately ten or twelve square inches. Water garden crops sometimes in hot weather. One great advantage
attending the cultivation of the carrot is, that it requires no manure whatever; any soil that is poor and light, especially if sandy, suits it, where it seldom exceeds the size of one’s thumb or middle finger; in rich manured earth, it grows much larger, but is not so sweet or good in quality.” (Justice and Dickson.)

3707. Taking the crop and preserving it by housing. “In the successive crops, begin to draw as above in a thinning order, that such others as are coming forward, have room to enlarge in succession; by which means a regular supply will be procured till March or April of the second season; specific sorts being sufficiently hardy to continue good throughout our ordinary winters. But of the winter crops for the table, draw a portion occasionally in November, December, or whenever there is an appearance of the first frost. Cut the tops off close, and house the roots in some lower shed or cellar, laid in sand, ready for use while the ground is frozen.” Instead of cutting the top and roots close off, some prefer leaving about an inch of the top, and the whole of the root; and, when the bulbs are kept in a sufficiently cool estate, this seems preferable, as more likely to retain the sap. (Abercrombie.)

3708. Turnip-tops. These are to be gathered from among the earliest spring-produced leaves, either from the crown, or flower-stalk. They are equally good from any of the varieties, and less acrid from those of the Swedish. Sometimes very late sowings are made in September and October, which never bulk, but which are preserved entirely for thin produce, as greens in spring.

3709. Field-turnips. Where a family can be supplied from the field, the roots will always be found of a better flavor than those produced in the garden; and the same remark applies to all the brassica tribe, excepting the cauliflower and broccoli, and to potatoes and most tuberous roots.

3710. To save seed. “Either leave in the spring, some of the best sound roots of the winter-standing crop, or leave, in May or June, a part of the spring-sown crop of the same year: or, to be more certain of good kinds, transplant, in November or February, a quantity of full-grown well-shaped roots of the autumn or winter crop, into large, deepish drills, two feet asunder; inserting the bottom fibre into the nether ground, and the main root fully to the bottom of the drill; and earth well over. The plants will shoot in large branchy stalks in summer, and ripen seed in July or August.” (Abercrombie.) It is preferable, however, to procure turnip-seed, as indeed that of most other vegetables, from the regular seedsmen; as the seed-farmers have opportunities of keeping the sorts distinct, which cannot be had within the precincts of a walled garden.

3711. Insects and diseases. (See Process in Sowing, supra.) The club or anbury is the principal disease to which turnips in gardens are liable, for which we know of no palliative but good culture, as turnips cannot be transplanted like the cabbage tribe. (See Sect. I. Subsect. 8.)

3712. The carrot is a hardy biennial, and common in many parts of Britain, in sandy soils, and by road-sides. It is known in many places by the name of bird’s nest, from the appearance of the umbel when the seeds are ripening. The leaves are pinnaatifid and much cut: the plant rises to the height of two feet, and produces white flowers in June and July, succeeded by rough, hispid seeds, which ripen in August. The root of the plant, in its wild state, is small, dry, sticky, of a white color, and strong-flavored; but the root of the cultivated variety is large, succulent, and of a red-yellow, or pale straw-color.

3713. Use. It is used in soups and stews, and as a vegetable dish. Parkinson informs us, that in his day, ladies wore carrot-leaves in place of feathers. In winter, an elegant chimneypiece ornament is sometimes formed, by cutting off a section from the head or thick end of a carrot containing the bud, and placing it in a shallow vessel with water. Young and delicate leaves unfold themselves, forming a radiated tuft, of a very handsome appearance, and heightened by contrast with the season of the year.

3714. The varieties of the carrot in common cultivation are

<table>
<thead>
<tr>
<th>Large red, or field carrot; grows to a large size, and is chiefly cultivated in fields and in farmers' gardens for coloring butter</th>
<th>Orange carrot; large, long root, of an orange color; best sort for the main crop</th>
<th>Small early crop. Also for shallow soils.</th>
<th>Early horn; short, smaller root; for a late crop.</th>
</tr>
</thead>
</table>

3715. Christie enumerates the following varieties, as having been grown in the garden of the Horticultural Society, some of which are foreign sorts newly introduced: —

<table>
<thead>
<tr>
<th>Horn carrots.</th>
<th>Early red, common early, long horn</th>
<th>Red, purple, and the allington, or superb, originally from Cheshire. (Hort. Trans. vol. iv. p. 383.)</th>
</tr>
</thead>
</table>

3716. Soil. The carrot is a light mellow soil, mixed with sand, which should be dug or trenched one or two spades deep, breaking well all the lumpy parts, so as to form a porous bed, and an even surface. The orange and red sorts, on account of their longer roots, require a soil proportionally deeper than the horn.

3717. Seed estimate, and sowing. The seeds have numerous forked hairs on their borders, by which they adhere together, and therefore should, previously to sowing, be rubbed between the hands, and mixed with sawdust in order to separate them as much as possible. They are also very light, and therefore a calm day must be chosen for sowing; and the seeds should be disseminated equally, and trodden in before raking. Previously to sowing, if convenient, the seed should be preserved, by sowing a few in a pot, and placing it in a hot-bed or hot-house, as it is more frequently bad than most garden-seeds. For a bed four and a half feet by thirty, one ounce will be requisite, and the same for one hundred and fifty feet of drill-row.

3718. Times of sowing. To have early summer carrots, sow on a warm border in the beginning of February; or, to have them still more forward, sow in a moderate hot-bed, giving copious admissions of air. In the open garden, begin with the early horn in the last fortnight of February, or first week of March, as dry, fine, and open weather may occur. The first-sown beds should be assigned a favorable situation, and covered for a time with haulm. Follow with the orange in the first fortnight of March,
and make successive sowings thence to the 30th of April, for main crops. Add smaller sowings twice in May, for plants to come young late in summer; also sow a few to make green manure in June for a later succession of young carrots in September. Lastly, in the beginning of August, two separate small sowings may be made, for plants to stand the winter, and afford young roots early in spring, March and April. 3719. Culture. "When the plants are up two or three inches in growth, in May and June, they will require thinning and clearing from weeds, either by hand or small hoeing. Thin from three to five inches' distance such as are designed for drawing in young and middling growth. But the main crop, intended for larger and full-sized roots, thin to six or eight inches' distance. Keep the whole clean from weeds, so as to prevent growing; and if the growth will be for drawing in June and July; large sizeable roots, in August and September; and those of full growth, by the end of October." (Abercrombie.)

In preparing during winter. "Carrots are taken up at the approach of winter, cleaned, and stored among sand. They may be built very firm, by laying them heads and tails alternately, and packing with sand. In this way, if frost be excluded from the store-house, they keep perfectly well till March or April of the following year. Some persons insist that the tops should be entirely cut off at the time of storing, so as to prevent their growing; while others wish to preserve the capability of vegetation, though certainly not to encourage the tendency to grow."

3721. To save seed. Plant some largest best roots in October, November, or the last fortnight of February, two feet apart; insert them a few inches over the crowns. They will yield ripe seed in autumn, of which gather only from the principal umbel, which is likely not only to afford the ripest and largest seed, but the most vigorous plants. A considerable quantity of carrot-seed for the supply of the London seedmen is raised near Weathersfield, in Essex; and much is imported from Holland.

3722. Insects. Carrots, when they come up, are apt to be attacked by insects like the turnips; the most approved remedies for which are thick sowing, in order to afford both a supply for the insects and the crop; and late sowing, especially in light soils, thus permitting the grubs to attain their fly state before the seed comes up.

3723. The parsnep is a biennial British plant, common in calcareous soils by road-sides near London. The wild variety is figured in English Botany, t. 556. The garden-parsnep has smooth leaves, of a light or yellowish-green color, in which it differs from the wild plant, the leaves of which are hairy and dark-green; the roots also have a milder taste: it does not, however, differ so much from the native plant, as the cultivated does from the native carrot.

3724. Use. The parsnep has long been an inmate of the garden, and was formerly much used. In Catholic times, it was a favorite Lent root, being eaten with salted fish. "In the north of Scotland," Neill observes, "parsneps—often beat up with potatoes and a little butter;" of this excellent mess the children of the peasantry are very fond, and they do not fail to thrive upon it. In the north of Ireland, a pleasant table beverage is prepared from the roots, brewed along with hops. Parsnep wine is also made in some places; and an excellent ardent spirit, distilled after a similar preparatory process, to that bestowed on potatoes destined for that purpose.

3725. Varieties. There is only one variety in general cultivation in Britain; but the French possess three, the Coquaine, the Lisbonaise, and the Stiam.

The Coquaine, Dr. Maculloch informs us (Colloq. Com. p. 195), is much cultivated in Guernsey and Jersey. The roots run sometimes fourteen deep, and are rarely so small in circumference as six inches, having been known to reach sixteen. The leaves of this variety grow to a considerable height, and the roots are formed from the whole crown of the root. The Lisbonaise does not extend to so great a depth as the coquaine; but the root is equally good in quality, and what is lost in length is gained in thickness. The leaves are small and short, and only proceed from the centre of the crown. The Stiam has a root of a yellowish color, not very large, but tender, and more rich in taste than the other varieties.

3726. Soil. The soil most proper for the parsnep should be light, free from stones, and deep. It should be dug or trenched before sowing at least two spits deep; and the manure should either be perfectly decomposed, or, if recent, deposited at the bottom of the trench.

3727. Seed estimate, and sowing. Sow in the end of February, or in March, but not later than April; and for a bed five feet by twenty, the plants to remain thinned to eight inches' distance, half an ounce of seed is the usual proportion. Having prepared either beds, four or five feet wide, or one continued plot, sow broad-cast, moderately thin, and rake the seed well into the ground.

3728. Culture. When the plants are about one, two, or three inches high, in May or June, let them be thinned and cleared from weeds, either by hand, or by small hoeing; thinning them from eight or twelve inches' distance. Keep them afterwards clean from weeds till the leaves cover the ground, after which no further culture will be required. The roots will be pretty large by the end of September; but at this time a few in their advancing young growth. Some of small parsnep is far best at full maturity, about the close of October, indicated by the decay of the leaf. The root will remain good for use till April and May following.

3729. Preserving during winter. The parsnep is not so liable as the carrot to be hurt by frost, if left in the ground. But it would be proper, in the beginning of November, when the leaves decay, to dig up a portion of the roots, and to cut the tops off close, laying them in sand, under cover, ready for use in hard frosty weather. The rest will keep good in ground till they begin to shoot in the spring; then, in February or March, dig them up; cut the tops off; and, preserved in sand, the root will remain till about the end of April.

3730. To save seed. "Transplant some of the best roots in February, two feet asunder, inserted in the crowns; they will shoot up in strong stalks, and produce large umbels of seed, ripening in autumn." (Abercrombie.)
PRACTICE. 

Part III.

Subsect. 6. Red Beet.—Beta vulgaris, L. (Schk. Han. i. t. 56.) Pent. Dig. L. and Chenopodien, B. P. Betterave, Fr.; Rothe Rübe, Ger.; and Barba Bietola, Ital.

3731. The red beet is a biennial plant, rising with large, oblong, thick, and succulent leaves, generally of a reddish or purple color; the roots often three or four inches in diameter, of a foot or more in length, and of a deep-red color. It produces greenish flowers in August. The red beet is a native of the sea-coast of the south of Europe; it was cultivated in this country by Tradescant, the younger, in 1656, and then called beet rave (or beet-radish), from the French name betterave.

3732. Use. The roots are boiled and sliced, and eaten cold, either by themselves, or in salads; they also form a beautiful garnish, and are very much used as a pickle. Some consider the green-leaved variety as more tender in the roots than the red-leaved sort; other prefer those with a few small dark-red leaves. From one variety, having a red skin, but white flesh, sugar is prepared in some parts of France and the Netherlands; but this manufacture, introduced under Buonaparte's reign, is now almost entirely given up in favor of West India produce. The roots, dried and ground, are sometimes used as "a supplement to coffee," and dried in an oven in thin slices; they are also used in comfits. (N. Cours d'Agricultur, art. Bette.)

3733. Varieties. These are numerous, but the principal are—

<table>
<thead>
<tr>
<th>The common long-rooted; which suits</th>
<th>The short, or turnip-rooted; suited to</th>
<th>The green-leaved; red-rooted, suited to</th>
</tr>
</thead>
<tbody>
<tr>
<td>light, deep, rich soils, and grows very</td>
<td>shallow soils</td>
<td>soils of light open texture.</td>
</tr>
</tbody>
</table>

3734. Morgan has enumerated the following sorts of red beet, as having been cultivated in the garden of the Horticultural Society:

- **Dwarf; one of the best**
- **Turnip-rooted; and early variety.**
- **Small-red; long-rooted; much esteemed**
- **In France, and said to have been raised,**
- **Green-topped; much grown in Holland.**
- **Rates some yellow-rooted sorts, none of which are in general cultivation.**

3735. Seed and soil. The beet is always raised from seed, and for a bed four feet and a half by twelve feet, one ounce is requisite. The soil in which it naturally delights is a deep rich sand, dry and light rather than moist. Sowing in seed-beds and transplanting has been tried; but though it may answer for the spinach or pot-herb beets, (white and its varieties,) it will not answer where the object is a large clean root.

3736. Sowing. The beet is sown annually in the last week of March, or beginning of April. If sown earlier, many of the plants are apt to run into flower, and so become useless. "The ground on which it is sown should have been previously enriched by mellow compost and sea-sand; but rank dung is not to be laid there, as it is apt to induce canker. For the long-rooted kind, trench to the depth of eighteen inches. Sow either broadcast on the rough surface, and rake well into the earth; or, as the seed is large, sow in drills an inch or two deep, and a foot asunder; or dot it in with a thick blunt-ended dibble, in rows that distance, making holes ten or twelve inches apart, about an inch and a half deep; drop two or three seeds in each hole, but with the intention to leave only one best plant."

3737. Subsequent culture. "When the young plants are advanced into leaves, one, two, or three inches in growth, they must be thinned and cleared from weeds, either by hand or small-hoeing, especially those sown promiscuously broadcast and in drills; thin the latter to twelve inches' distance; and those holed in by dibble, to one in each place. They will acquire a large full growth in the root by September or October, to take up for use as wanted, and in continuance all winter and spring following: or in November, it may be proper to dig up a quantity, cut off the leaves, and deposit the roots in dry sand; under cover, ready for use in winter, in case of hard frosty weather, which would fix them fast in the ground; or the rest may be dug up at the same time, and trenched in close together in some dry compartmecnt, to be covered occasionally in severe frost, to prevent their being frozen in, that they may be readily taken up as wanted. Towards spring, in February or the beginning of March, if any remain in the bed where raised, their removal then, being trenched in close together over the root, will, in some degree, check their shooting, and preserve them from running, so as to keep them good all the spring till May and June." (Aberecrumble.)

3738. Housing. In the northern counties, the winter stock of beet is commonly lifted and housed in sand, in the manner of carrots. In digging up the roots for this purpose, great care must be taken that they be not in anywise broken or cut, as they bleed much. For the same reason, the leaves should be cut off, at least an inch above the solid part of the root.

3739. To save seed. Either leave a few strong roots standing in the rows; or select a few, and transplant them to a spot where they will be in no danger, when in flower, of being impregnated with any other variety. They will shoot up the second year, when their flower-stalks should be tied to stakes, to prevent their breaking over.

3740. The skirret is a perennial tap-rooted plant, a native of China, known in this country since 1548. The lower leaves are pinnated, and the stem rises about a foot high, terminated by an umbel of white flowers, in July and August. The root is composed of fleshy tubers, about the size of the little finger, and joined together at the crown or head; they were formerly much esteemed in cookery. In the north of Scotland, the plant is cultivated under the name of crummock.

3741. Use. The tubers are boiled, and served up with butter; and are declared by Worlidge, in 1682, to be "the sweetest, whitest, and most pleasant of roots."

3742. Culture. This plant grows freely in a lightish soil, moderately good. It is propagated both from seed, and by offsets of established roots. The better method is to raise seedlings, to have the root in perfection, young and tender.
SCORZONERA, SALSIFY.

3743. By seed. "Sow between the 21st of March and the 15th of April; a fortnight later rather than any earlier for a full crop, as plants raised forward in spring are apt to start for seed in summer. Sow on an open ground or in drills six inches apart. When the plants are one or two inches high, thin them to five or six inches asunder. They will enlarge in growth till the end of autumn; but before the roots are full grown, in August, September, or October, some may be taken up for consumption as wanted: those left to reach maturity will continue good for use throughout winter, and in spring, till the stoms run." 3744. By slips. "Having some plants of last year's raising, furnished with root-offsets, slip them off; taking only the young outward slips, and not leaving any of the larger old roots adhering to the detached offsets, which plant liable to disease, in rows from six to nine inches asunder. They will soon strike, and enlarge, and divide into offsets: which, as well as the main roots, are catable and come in for use in proper season." 3745. To save seed. Leave some old plants in the spring: they will shoot up stalks, and ripen seed in autumn.

SUBJECT 8. Scorzonera, or Viper's Grass.—Scorzonera Hispanica, L. (Lam. Ill. t. 647. f. 5.) Synag. Polyg. Èqu. L. and Cichoraceæ, J. Scorzònere, or Salsafis d'Espagne, Fr.; Scorzònere, Ger.; and Scorzonera, Ital. 3746. The scorzonera is a hardy perennial, a native of Spain, the south of France, and Italy, cultivated in this country since 1576. The stem rises two or three feet high, with a few embracing leaves, and is branched at top; the lower leaves are linear, eight or nine inches long, and end in a sharp point; the flowers are yellow, and appear from June to August. The root is carrot-shaped, about the thickness of one's finger; tapering gradually to a fine point, and thus bearing some resemblance to the body of a viper. 3747. Use. The outer rind being scraped off, the root is steeped in water, in order to abstract a part of its bitter flavor. It is then boiled or stewed in the manner of carrots or parsnips. The roots are fit for use in August, and continue good till the following spring.

3748. Culture. "To have an annual supply, sow every year; for although the plant, as to its vegetable life, be perennial, the root continuing only a few years useful, must be treated merely as a biennial. The quantity of seed for a bed four feet and a half by ten feet, to be sown in drills fifteen inches asunder, is one ounce. Sow every spring, at the end of March, or in April: follow with a secondary sowing in May. This root likes a deep, light soil. Allot an open compartment. Sow either broad-cast, and rake in evenly; or in small drills, twelve or fifteen inches asunder, and earth over half an inch or an inch deep. When the young plants are two or three inches high, thin them to six or eight inches' distance. Clear out all weeds as they advance in growth. The plants having a free increase all summer, the roots will, some of them, be a tender shoots begin to take up growth in August, others in September, but will not attain full growth till the end of October, when, and during the winter, they may be used as wanted; or some may be dug up in November, and preserved in sand under cover, to be ready when the weather is severe. The plants left in the ground continue useful all winter till the spring; then those remaining undrawn, shoot to stalk in April and May, and become unfit for the table." 3749. To save seed. "Leave some old plants in the spring; which will shoot up in tall stems, and produce ripe seed in autumn." (Abercrombie.)

3750. The salsify is a hardy biennial, a native of England, but not very common. The root is long and tapering, of a fleshy white substance; the herb smooth, glaucous, and rising three or four feet high. The leaves, as the trivial name imports, resemble those of the leek; the flowers are of a dull purple color, closing soon after mid-day; the seed, as in other species of goat's-beard, is remarkable for having attached to it a broad feathery crown. It has taken place in gardens of the T. pratensis, which was cultivated in Ger- racket's and Parkinson's time, but is now entirely neglected.

3751. Use. The roots are boiled or stewed like carrots, and have a mild, sweetish flavor; the stalks of year-old plants are sometimes cut in the spring, when about four or five inches high, and dressed like asparagus.

3752. Culture. "Salsify is raised from seed, annually, in the spring, and for thirty feet of drill, one ounce of seed is sufficient. Allot an open situation. The soil should be light and mellow, full two spits deep, that the long tap-root may run down straight. Sow in March, April, and in May, for first and suc- cession crops, either broad-cast in beds, and rake in the seed, or in small drills, eight or ten inches asun- der. The plants are to remain where sown. When they are two or three inches high, thin them about six inches apart. In the dry hot weather of summer, water now and then till the ground be soaked. The roots having attained a tolerable size in August and September, may be taken up occasionally for present use, which plant re-digging, in pairs from six to nine inches asunder. They will soon strike, and will continue good all winter, and part of the following spring. For winter use, take up a portion before frost hardens the ground, and preserve in sand. Such year-old plants as remain undrawn in the following spring, shoot up with thick, fleshy, tender stalks: these are occasionally gathered young to boil; the roots continuing good till the plant runs to stalk in April or May."

3753. To save seed. "Leave or transplant some of the old plants in spring; which will shoot, and produce ripe seed in autumn." (Abercrombie.)

3754. The radish is an annual, a native of China, and mentioned by Gerrard in 1584. "The leaves are rough, lunate, or divided transversely into segments, of which the inferior less ones are more remote. The root is fleshy, and fusiform in some varieties, in others sub-globular; white within, but black, purple, yellow, or white, on the outside; the flowers pale-violet, with large, dark veins; pods long, with a sharp beak."

3755. Use. Formerly the leaves were often boiled and eaten; but now the roots are chiefly employed. These are eaten raw in spring, summer, autumn, and winter. The young seedling leaves are often used with cresses and mustard, as small salad; and radish seed-pods, when of plump growth, but still young and green, are used to increase the variety of vegetable pickles, and are considered a tolerable substitute for capers.

3756. Varieties. These may be divided into the spring, autumn, and winter sorts. Spring radishes may be subdivided into the long or spindle-rooted (Rave, Fr.); and the round or turnip-rooted (Radis, Fr.); the autumn sorts are chiefly oval or turnip-rooted, and the winter radishes are ovate or oblong, and dark-colored. "The character of a good long-rooted radish," Strachan observes, "is to have its roots straight, long, free from fibres, not tapering too suddenly, and especially to be fully formed on the top, or well Shouldered, as it is called, and without a long neck; the roots should be ready to draw whilst the leaves are small, whence the name short-top radish, and if they soon attain a proper size, and also force well, they are then called early and frame radishes." (Hort. Trans. vol. iii. p. 458.)

Spring and Summer Kinds. Long roots. Scarlet, or salmon-colored, round, or wrinkled, hardy. Short-rooted scarlet, and Early frame scarlet; which are the two principal varieties generally cultivated. Purple; an early sort of good flavor, but at the same time bitter. Long white; the original variety cultivated in England; time semi-transparent, and delicate. Tall Radishes. White; root globular like a turnip. Early white; a subvariety. Tall Radish. Scarlet, or salmon-colored, scarlet, and crimson; so named are applicable to one sort which approaches to the pear-shape.

3757. Estimate of sorts. The spindle-rooted kinds are cultivated in the largest proportion for the first crops. Root-ball turnip-rooted sorts may be sown in spring as secondary crops, and in summer and autumn for more considerable supplies. The winter sorts have a coarser flavor than the other kinds; but being of a hardy nature, are frequently sown. They are sown in salads, or occasionally eaten alone with salt, vinegar, and other condiments.

3758. Propagation. All the varieties are raised from seed.

3759. Soil and situation. The soil should be light and mellow, well broken down by digging: for sowings between the middle of October and the middle of February, let the site be a dry sheltered border, open to the full sun at the end of January, but to the middle of February free from the winter air. An open and sunny exposure; also soil, firm, solid, and rich, free from the slightest admixture of gravel and coarse sand. The site should be exposed to the sun all day, and in the middle of summer it should be kept open; but if it be shaded, the soil should be kept as dry as possible. Those varieties are the most valuable, which are good sown in May, for they will yield the largest harvest. Radishes planted in May, will yield the greatest harvest in June, August and September.

3760. Times of sowing. "The crops raised between the middle of October and the middle of February, are usually confined to the spindle-rooted kinds. Of the early short-rooted red, a small first saving may be made at the end of October, another at the end of November, and a third in the last fortnight of December, when the open temperate weather; respectively to stand over the winter; but make the principal early sowings in January, or the beginning of February. From this time sow every fortnight or ten days, in full succession crops till the end of May; as well the white and red small turnip-rooted as the autumn sorts. The winter sorts are sometimes raised at the beginning of summer; but the finest season to sow them is from the first of June to the end of August; that is, in July for use in autumn, and in August to provide a supply throughout winter."

3761. Seed, process in sowing, and common culture. "Sow each sort separate; and for a bed four feet six inches by twelve feet, two ounces of seed will be required of the spring sorts, and an ounce and half for the autumn varieties. All the kinds may be sown either broad-cast or in drills; but the latter is preferable, as allowing the roots to be drawn regularly, with less waste. If you sow broad-cast, it is a good method to sow the drill one-fourth of a foot wide, with an alley between, a foot wide, the earth of which may be used to raise the beds, or not, as the season may make it desirable to keep the beds dry or moist. Avoid sowing excessively thick, as it tends to make the tops run, and the roots stringy. Rake in the seed well, full half an inch deep, leaving none on the surface to attract the birds. If you true drills, sow them about three and a half inches apart for the spindle-rooted kinds half an inch deep, and about two and a half inches apart; for the small turnip-rooted, three quarters of an inch deep, and four or five inches asunder; and for the black turnip or Spanish, six or eight inches asunder, because the root grows to the size of a middle-sized turnip. As the plants begin to grow, thin them so as to leave for each bed, three roots in the row, one inch apart, and the other sorts three, four, or five, leaving the most space to the respective sorts in free-growing weather. In dry warm weather, water plenty frequently: this swells the roots, and makes them mild and crisp."

3762. Occasional shelter. "The crops sown between the end of October and the end of February, besides being favored in situation, will want occasional shelter, according to the weather. On the first approach of frost, whether the seed is just sown, or the plants have appeared, cover the ground, either with chaff, straw, dry long hair, or dried fern, two or three inches thick, or with mats supported on short stout pegs. The covering will keep off the birds, and by its warm effect on the mould, forward the germination of the seed. The time for removing or restoring it must be regulated by the weather; as the plants should be exposed to the full air whenever it can be safely done. If the season be cold without frost, take off the covering every morning, and put it on towards evening; and if the weather be sharp and frosty, let it remain on night and day, till the plants have advanced into the first rough leaves, and af-
SPINACEOUS PLANTS.

635
towards occasionally, till the atmosphere is settled and temperate. Replace it constantly at night till there is no danger of much frost happening; then wholly discontinue the covering."

3763. Pots for pickling. "Radish seed-pods should be taken for pickling when of plump growth, in July and August, while still young and green."

3764. To save seed. "Transplant a sufficiency of the finest plants in April or May, when the main crops are in full perfection. Draw them for transplanting in moist weather, selecting the straightest, best-colored roots, with the shortest tops, preserving the leaves to each; plant them, by dibble, in rows two feet and a half distant, inserting each root wholly into the ground, down to the leaves. Keep the red and salmon-colored kinds in separate situations, to prevent a commixture of their farina, and to preserve the kinds distinct. With proper watering, they will soon strike, and shoot up in branchy stalks, producing plenty of seed; which will be ripe in September or October. In transplanting for seed the turnip-rooted kinds, select those with the nearest-shaped rounded roots, of moderate growth, and with the smallest tops. They, as the others, will yield ripe seed in autumn. To obtain seed of the winter sorts, sow in the spring to stand for seed; or leave or transplant, in that season, some of the winter-standing full roots. As the different kinds ripen seed in autumn, cut the stems; or gather the principal branches of pods; and place them in an open airy situation, towards the sun, that the pod, which is of a tough texture, may be dry, and become brittle, so as readily to break, and give out the seed freely, whether it be threshed or rubbed out."

3765. For forcing the radish, see Chap. VII. Sect. XIII.

SECT. IV. Spinaceous Plants.

3766. As the excellence of spinaceous plants consists in the succulence of the leaves, almost everything depends on giving them a rich soil, stirring it frequently, and supplying water in dry seasons. The space they occupy in the garden is not considerable, say a thirtieth part; more especially as some of them, the common spinage for example, often comes in as a temporary crop between rows of peas, or beans, or among cauliflowers and broccoli, &c. The plant of this class the most deserving of culture in the cottage garden, is the Swiss chard, which produces abundance of succulent, and most nutritious foliage. It is to be found in every cottage garden in Switzerland and the north of France.

3767. The common spinage is an annual plant, cultivated in this country since 1568, and probably long before; but of what country it is a native is not certainly known; some refer it to Western Asia. The leaves are large, the stems hollow, branching, and, when allowed to produce flowers, rising from two to three feet high. The male and female flowers, as the name of the class imports, are produced on different plants; the former come in long terminal spikes; the latter in clusters, close to the stalk at every joint. It is almost the only dioecious plant cultivated for culinary purposes.

3768. Use. The leaves are used in soups; or boiled alone, and mashed and served up with gravies, butter, and hard-boiled eggs. The leaves may be obtained from sowings in the open ground at most seasons of the year, but chiefly in spring, when they are largest and most succulent.

3769. Varieties. These are —

The round-leaved, or smooth-seeded | The oblong triangular-leaved, or prickly seeded.

3770. Estimate of sorts. "These varieties of spinage are adapted for culture, principally, at two different seasons. The round-leaved sort, of which the leaves are larger, thicker, and more juicy, is mostly sown in spring and summer, for young spinage in those seasons: the triangular-leaved is chiefly sown in autumn, to stand for winter and the following spring; for the leaves being less succulent, it is harder to stand the inclement weather: but a portion of this is acceptable, when the other sort is principally raised."

3771. Summer crop. "Begin in January, if open weather, with sowing a moderate crop of the round-leaved. Sow a larger quantity in February; and more fully in March. The plants presently fly to seed in summer, especially if they stand crowded; it is therefore proper to sow about once in three weeks, from the beginning of March to the middle of April; then, every week till the middle of May: from which time, till the end of July, sow once a fortnight. Small crops, thus repeated, will keep a succession during the rest of summer and throughout autumn. A portion of the prickly seeded spinage may be sown as thought proper, to come in among the successive summer crops; and if drilled between lines of other vegetables, will enroach less than the smooth-seeded, a thing to be considered where the spare room is not of a liberal width."

3772. Soil and situation. "The soil which suits any of the general summer crops will do for spinage; that for the early crop should be lightest and driest. For a January sowing, allot a warm border, or the best sheltered compartment. Afterwards, for all the supplies during summer, sow in an open compartment. Where it is necessary to make the utmost of the ground, the spring sowings, in February, March, and April, may be made in single drills between wide rows of young cabbages, beans, peas, or other infant crops of slow growth; or they may be made still better on spots intended to receive similar plants, including cauliflowers and horse-radish; and the spinage will be off before the slower-growing crops advance considerably; or spinage and a thin crop of radishes may be sown together; and the radishes will be drawn in time, to give room for the spinage."

3773. Seed and process in sowing. "When raised by itself, spinage is generally sown broad-cast, and two ounces will sow a bed four feet and a half by thirty feet: but in drills one ounce will sow the same space. In drills, it is easier to weed and gather: let the drills be from nine to twelve inches apart. Beus
four feet wide, with small alleys, are convenient of access. Let the ground be thoroughly dug. Whether broad-cast or in drills, sow thinly; and rake or earth in about an inch deep.”

3776. Subsequent culture. “When the plants are up, showing leaves about an inch broad, clear them from weeds, either by hand or small hoeing; and thin the plants where crowded (especially the broad-cast crops), about a foot apart, or, if advanced in growth, every other may be cut out for the sake of the distance to about six inches, that the remainder may grow stocky, with large spreading leaves. The plants of the early and succession crops attain proper growth for gathering in April, May, and June. When the leaves have four to six inches in breadth, cut the plants clean out to the bottom, or only the larger leaves. But as soon as there is any appearance of their running to seed, they may be drawn out clean as wanted.”

3775. Winter crop. “The prickly seeded, or triangular-leaved, is alone constituted to stand a severe winter. The quality of seed is better in spring than in winter, and hence as a winter crop should be sown in the first or second week of August, and a secondary one towards the end of that month, to stand later in the spring, until the round spinage comes in. The plants of these sowings will acquire proper growth and strength, and may run the same year, or very early in the spring, which is apt to be the case with crops sown sooner.”

3776. Site. “Allow a compartment of dry-lying mellow ground, with an open aspect to the winter’s sun; and let it be digged regularly.”

3777. Sowing. “In general, sow broad-cast, treading the seed down, and raking it into the ground. The bed may be one continued space; or the garden may be divided into beds three or four feet wide, with spade-wide alleys between them, which are convenient both in the culture and the gathering of the crop. A portion may be sown thinly in broad shallow drills, from six to twelve inches in width. When the plants are advancing with leaves an inch broad, in September, they will require thinning and clearing from weeds; which may be done either by hand or by small-hoeing; thin the plants to two or three inches’ distance. If by October and November the plants are forward in growth, with leaves two or three inches broad, some may be gathered, occasionally, in the larger leaves; or, where most crowded, plants may be cut out to give the others room for a strong stocky growth, so as to be more able to endure the cold and wet in winter, and produce larger and thicker leaves. In this stage, clear out all weeds by hand, as any left in hoeing would grow again, especially if the season is mild. If in the hard winter, these earths, some may be partially gathered as wanted, taking the larger outward leaves: the others will increase in succession. At the end of winter, thin the plants to seven inches by seven, ten by five, or twelve by five. On a surface of hard earth, if it has been treading the earth, the plants will reach full growth in February, March, and April, bearing, for frequent gathering, numerous clusters of large leaves. In April and May, the larger plants may be cut out fully for use, clean to the bottom, or drawn, if the ground be wanted; as they will then soon go to seed-stalks, past useful growth, and will be succeeded in May and June by the young spring-sown crops of round spinage.”

3778. To save seed. “To obtain seed of the round-leaved, leave a sufficient quantity of established plants in April, May, or June, to run up in stalks; or transplant in autumn some of the spring-sown which have not run. To save seed of the triangular spinage, transplant in March some good strong plants, of the winter crop. For large supplies, a portion of each may be sown in February, or the first fortnight of March, to stand wholly for seeding. Sow each sort separate. Respecting both sides, observe, that they are of the class Diccia, the male and female flowers growing separately, on two distinct plants. When the plants are flowering for seed, the cultivator should examine whether the female plants, distinguishable by the abundant farina upon the blossoms, stand crowded or numerous to excess; in which case he should pull up the superfluous plants, leaving a competency for fertilising the female blossoms, which else would prove abortive. And when the female blossoms are set, it is best to dispose of all the male plants, drawing them by hand; which will give more room to the females to grow and perfect their seed. The plants rejected may be profitably given to young pigs. The seed ripens in July and August.” (Abercornble.)

Subsect. 2. White Beet. — Beta Cicla, L. Pent. Dig. L; and Chenopodex, B. P. Bette, or Poitre, Fr.; Mangold Kraut, Ger.; and Biettola, Ital.

3779. The white beet is a hardly biennial plant, with leaves larger than the red beet, and very thick and succulent. It is a native of the sea-coasts of Spain and Portugal, and was introduced in 1570, and cultivated by Gerrard and Parkinson. It produces greenish flowers in August and September.

3780. Use. The white beet is cultivated in gardens entirely for the leaves, which are boiled as spinage, or put into soups. Those of the great white, or sweet beet are esteemed for the midribs and stalks, which are separated from the lamina of the leaf, and stewed, and eaten as asparagus, under the name of chard. The variety called the Mangold Wurzel, Ger. (Mangold-root), is reckoned a valuable agricultural plant for feeding cattle, and affording sugar.

3781. Varieties. The principal of those known in this country are —

The common green-leaved small rooted beet; the roots not thicker than a man’s thumb
The common white small-rooted; the leaves whiter, and with white ribs and veins
The yellow-rooted beet; or Swiss beet; large
The beet, or white; or Savoy chard; large
Stalks, smaller erect leaves, with asparagus.

3782. Propagation and soil. It is raised from seed; and, for four feet and a half by twelve twow in drills, one ounce is requisite. The soil for the varieties to be used as pot-herbs, may be considerably stony; the loam for the tallest, increasing the ratio of yellow beets, and may not be quite so deep. The plants endure for two years, shooting the autumn of the second; but it is best not to depend on the shot or shoot leaves of the second year, but sow at least annually.

3783. Sowing. The white beet is sown in gardens in the beginning of March, and sometimes also in September, to furnish a supply of small beets in winter for use, increasing tender leaves late in winter. Sow either broad-cast, and rake in the seeds; or in drills, six or eight inches apart for the smaller kinds, and ten or twelve for the larger. For the mangold, eighteen inches are not too much.

3784. Culture. When the plants have put out four leaves, they are hoed and thinned out to four inches to a foot, according to the sort. A second thinning should take place a month afterwards, and the ground should be kept clear of weeds, and stirred once or twice during the season with a fork or pronged
hoe. In cultivating the Swiss chard, the plants are frequently watered during summer, to promote the succulence of the stalks; and in winter they are protected by litter, and sometimes earthed up, partly for this purpose, and partly to blanch the stalks. Fresh chards are thus obtained from August to May. The mangold is often transplanted, especially in field culture, but this being foreign to our present purpose, we take leave of it. When the garden sorts of white beet are transplanted, the proper time is during moist weather in May or June. The distance from plant to plant may be from ten to fourteen inches, much of the advantage of transplanting depending on the row thus afforded the plants; together with the general disposition of transplanted annuals, with uniform roots, as the turnip, carrot, &c. to throw out leaves and lateral radicles.

3785. Gathering. The most succulent and nearly full-grown leaves being gathered as wanted, others will be thrown out in succession. The root is too coarse for table use.

3786. To save seed. Proceed as in growing the seed of red beet.

Subsect. 3. Oroche, or Mountain Spinage. — *Attrixps hortenalis*, L. (Blackw. t. 99.)

3787. The *oroche* is a hardy annual, a native of Tartary, and introduced in 1548. The stem rises three or four feet high; the leaves are oblong, variously shaped, and cut at the edges, thick, pale-green, and glaucous, and of a slightly acid flavor. It produces flowers of the color of the foliage in July and August. There are two varieties, the white or pale-green; and the red or purple-leaved.

3788. Use. The leaves are used as spinage, and sometimes also the tender stalks. The stalks are good only while the plant is young; but the larger leaves may be picked off in succession throughout the season, leaving the stalks and smaller leaves untouched, by which the latter will increase in size. The spinage thus procured is very tender, and much esteemed in France.

3789. To save seed. Leave a few plants of the most tender and succulent constitutions to blossom, and they will produce abundance of seeds in August.

3790. The *wild spinage* is an indigenuous perennial, common by way-sides in loamy soils. The stem rises a foot and a half high, is round and smooth at the base, but upwards it becomes grooved and angular. The leaves are large, alternate, triangular, arrow-shaped, and entire on the edges. The whole plant, but especially the stalks, is covered with minute transparent powdery particles.

3791. Use. While young and tender, the leaves are used as a substitute for spinage, for which purpose, Curtis observes, it is cultivated in Lincolnshire, in preference to the garden sort. Withering observes, that the young shoots, peeled and boiled, may be eaten as asparagus, which they resemble in flavor.

3792. To save seed. Leave a few plants of the most tender and succulent constitutions to blossom, and they will produce abundance of seeds in August.

Subsect. 5. New Zealand Spinage. — *Tetragonia expansa*. (Plant. grass. 113.) Cos. Di-Pentag. L. and Ficoside, J.

3794. New Zealand *spinage* is a half hardy annual, with numerous branches, round, succulent, pale-green, thick, and strong, somewhat procumbent, but elevating their terminations. The leaves are fleshy, growing alternately at small distances from each other, on shortish petioles; they are of a deltoid shape, but rather elongated, being from two to three inches broad at the top, and from three to four inches long; the apex is almost sharp-pointed, and the two extremities of the base are bluntly rounded; the whole leaf is smooth, with entire edges, dark-green above, below paler, and thickly studded with aqueous tubercles; the mid-rib and veins project conspicuously on the under surface. The flowers are sessile in the axil of the leaves, small and green, and, except that they show their yellow antherae when they expand, they are very inconspicuous. The fruit when ripe has a dry pericarp of a rude shape, with four or five hornlike processes enclosing the seed, which is to be sown in its covering. It is a native of New Zealand, by the sides of woods in bushy sandy places, and though not used by the inhabitants, yet being considered by the naturalists who accompanied Captain Cook, as of the same
nature as the chenopodi um (see Foster, Plant. exculent., &c.), it was served to the sailors, boiled every day at breakfast and dinner. It was introduced here by Sir Joseph Banks in 1772, and treated as a green-house plant; but has lately been found to grow in the open garden as freely as the kidneybean or nasturtium. As a summer spinach it is as valuable as the orache, or perhaps more so. Every gardener knows the plague that attends the frequent sowing of common spinach through the warm season of the year; without that trouble it is impossible to have it good, and with the utmost care it cannot always be obtained exactly as it ought to be (particularly when the weather is hot and dry) from the rapidity with which the young plants run to seed. The New Zealand spinach, if watered, grows freely, and produces leaves of the greatest succulence in the hottest weather. Anderson, one of its earliest cultivators, had only nine plants, from which he says, "I have been enabled to send in a gathering for the kitchen every other day since the middle of June, so that I consider a bed with about twenty plants quite sufficient to give a daily supply, if required, for a large table."

3795. Use. It is dressed in the same manner as common spinach, and whether boiled plain, or stewed, is considered by some as superior to it; there is a softness and mildness in its taste, added to its flavor, which resembles that of spinach, in which it has an advantage over that herb.

3796. Culture. The seed should be sown in the latter end of March, in a pot, which must be placed in a melon-frame; the seedlings plants while small should be set out singly, in small pots, and kept under the shade in a frame, until about the twentieth of May, when the midsummer, the season will probably allow of their being planted out, without risk of being killed by frost. At that time a bed must be prepared for the reception of the plants, by forming a trench two feet wide, and one foot deep, which must be filled last to the surface with rotten dung from an old cucumber-bed; the dung be covered with six inches of garden-mould, thus creating an elevated ridge in the middle of the bed, the sides of which must extend three feet from the centre. The plants must be put out three feet apart; I planted mine at only two feet distance from each other, but they were too near. In five or six weeks from the planting, the leaves have grown large enough to allow the gathering of the leaves for use. In dry seasons the plants will probably require a good supply of water. They put forth their branches vigorously as soon as they have taken to the ground, and extend before the end of the season three feet on each side from the centre of the bed.

3797. In gathering for use, the young leaves must be pinched off the branches, taking care to leave the leading shoot uninjured; this, with the smaller branches which subsequently arise from the axils of the leaves which have been gathered, will produce a supply until a late period in the year, for the plants are sufficiently hardy to withstand the frost which kill nasturtiums, potatoes, and such tender vegetables. (Anderson, in Hort. Trans. vol. iv. 492.)

3798. To save seed. Place a plant or two in a poor soil, or train one up a wall, or stunt one or two in lime rubbish, or in pots sparingly watered, as in growing the pea-plant for seed. Or a few cuttings may be struck in autumn, and preserved through the winter in the green-house.

3799. French sorrel, Roman sorrel, or round-leaved sorrel, is the R. Scutatus, L.; a perennial plant, a native of France and Italy, and cultivated in this country since 1596. The leaves are somewhat hasteate, blunt, and entire; glaucous, smooth, soft, and fleshy. The trailing stems rise from a foot to a foot and a half high, and the flowers, of a greenish-white, appear in June and July.

3800. Garden-sorrel is the R. acetosa, L. (Eng. Bot. 127.), an indigenous perennial, common in meadows and moist situations. The root-leaves have long foot-stalks, are narrow-shaped, blunt, and marked with two or three large teeth at the base; the upper leaves are sessile and acute. There are two varieties of this species, the broad-leaved, and the long-leaved, both in cultivation, and the former esteemed the most succulent.

3801. Use. Both sorts are used in soups, sauces, and salads; and very generally by the French and Dutch, as a spinach; in the latter way it is often used along with herb-patience, to which it gives an excellent flavor, as well as to turnip-tops.

3802. Culture and soil. "The finer plants are propagated from seed, but good plants can be obtained by parting the roots, which is the most expeditious way. The native varieties flourish both in humid meadows and sandy pastures: their roots strike deep. The trailing round-leaved requires a dry soil."

3803. By seed. "Sow in any of the spring months, best in March. Drop the seed in small drills, six or eight inches asunder. When the plants are one or two inches high, thin them to three or four inches apart; when advanced to be a little stocky, in summer or autumn, transplant a quantity into another bed, from six to twelve inches apart, if of the first two sorts; leaving those in the seed-bed with the same intervals. But leave almost double that distance for the round-leaved creeping kind. They will come in for use the same year."

3804. By offsets. Part the roots in spring or autumn. Either detach a quantity of offsets, or divide full plants into rooted slips; plant them at a foot distance and water them well."

3805. General treatment. As these herbs, however originated, run up in stalks in summer, cut them down occasionally; and cover the stool with a little fresh mould, to encourage the production of large leaves on the new stem. Fork and clean the ground between the plants every autumn or spring; and keep it clear from weeds. If, in two or three years, they have dwindled in growth, bearing small leaves, let them be succeeded by a new plantation.

3806. To save seed. "Permit some old plants to run up in stalks all the summer: they will ripen seed in autumn." (Abercrombie.)
7387. The herb-patience, or patience-dock,—Rumex Patulina, L. (Blackw. 349.)

The herb-patience is a hardy perennial plant, a native of Italy, introduced in 1575. The leaves are broad, long, and acute-pointed, on reddish foot-stalks; the stems, where allowed to spring up, rise to the height of four or five feet. It produces its whitish-green flowers in June and July.

7388. Use. "In old times, garden-patience was much cultivated as a spinach. It is now very much neglected, partly perhaps on account of the proper mode of using it not being generally known. The leaves rise early in the spring; they are to be cut while tender, and about a fourth part of common sorrel is to be mixed with them. In this way patience-dock is much used in Sweden, and may be safely recommended as forming an excellent spinach dish." (Neill.)

7389. Culture. Garden-patience is easily raised from seeds, which may be sown in rows in the manner of other plants; it is kept out and treated afterwards like the latter plant. If the plants be regularly cut over two or three times in the season, they continue in a healthy productive state for several years.

Sect. V. Alliaceous Plants.

7390. The alliaceous esculent are of great antiquity and universal cultivation. No description of useful British garden is without the onion; and few in other parts of the world, without that bulb, or garlic. They require a rich, and rather strong, soil, and warm climate, thriving better in Spain and France than in England. The onion and leek crops may occupy a twentieth of the open compartments in most kitchen-gardens; and a bed of five or seven square yards in those of the cottager.

Subsect. 1. Onion.—Allium Cepa, L. (Hexandria Monogynia, L. and Asphodelaceae, J. Oignon, Fr.; Zwiebel, Ger.; and Cipolla, Ital.)

7391. The common bulbous onion is a biennial plant, supposed to be a native of Spain, though as Neill observes, "neither the native country, nor the date of its introduction into this island, are correctly known." It is distinguished from other alliaceous plants by its large fistular leaves, swelling stalk, coated bulbous root, and large globular head of flowers, which expand the second year in June and July.

7392. Use. The use of the onion, in its different stages of growth, when young, in salads, and when bulbiling and mature, in soups and stews, is familiar to every class of society in Europe; and for these purposes has been held in high estimation from time immemorial.

7393. The varieties ascertained to be best deserving of culture are as follows:—

The silver-skinned; flat, middle-sized, and shallot, chiefly used by the florists.

Early silver-skinned; a sub-sort of the above, smaller, and excellent for pickling.

Yellow; small, globular, strong-flavored, and good for pickling.

Two-blaided; flat, small, globular-green, has its seed in the leaves, and keeps well; one of the best for pickling.

Tree; long, large heads of the finest; large, flatly globular; mild; does not keep well.

Spanish, English, white Portuguese, Cambridge, Evesham, or sandy onion; large, flat, tinged with green, mild, but does not keep very well; good for a general crop, much cultivated round Reading.

Strasburgh, Dutch, or Flanders onion, the seed being generally procured from them; or Essex onion, when the seed is sown in that country; red, large, and light-red, tinged with green; hardy, but not strong; most of the best; much the most generally cultivated in England.

Depthed onion; middle-sized, globular, pale-brown; a sub-sort of the Strasburgh, and very generally cultivated.

Globe; large, globular, pale-brown, tinged with red, mild, and keeps well; very popular among gardeners.

James's keeping; large, pyramidal, brown, and strong; in flavor, no size, better than the preceding.

Rhubarbe Plantation onion; large, red, flat, strong flavor, and good for pickling.

Pale-red; middle-sized, flattened, globe-shaped, pale-red, strong flavor, keeps well.

Blood-red, Dutch blood-red, St. Thomas's; somewhat yellow, middle-sized, flat, very hard, deep red, strong flavor, and keeps par excellence; much grown in Wales and Scotland; in the London market it is esteemed for its diuretic qualities.

Trinidad: a large onion, oval; light red, tinged with green and brown; for soups, stews, or soups, and requires a great deal of time after it is taken up.

Lisbon: large, globular, smooth, bright, white, and thin skin, tarty, rich and ripening but hardly, much used for autumn soups; seed generally obtained from the south of France.

Welsh onion; cultivated (Allium fistulosum, L.); a native of Siberia, hardy, strong in flavor, but does not bulb; sown in autumn for drawing in spring.

Underground or potato onion; multiplies itself by the formation of young bulbs on the parent root, and produces an onion bulb below the surface; ripens early, but does not keep beyond February; flavor strong.

Tree or bulb-bearing onion (Allium cepa var. sphaerocephalum, Oignon d'Epinette; Fr.; originally from Canada, where the French introduced it); produces a large, strong, red flower, and seed, when they are allowed to throw up flower-stalks, the flower becomes stunted, and the bulbs instead of flowers; here it retains the same habit. It is more an object of curiosity than use, though, in some parts of Wales, Milne informs us (Hort. Trans. i. 419); the cauliflower bulbs are produced, and a ground of onions for this purpose is made; the stems supplies a succession of bulbs for next year's planting; it is considered stronger, and to go further as seasoning than other onions. (Hort. Trans. iii. 15.)

Scallion; a term generally given to the strong green tops of onions in the spring which do not bulb, or to the large leafy onions of the same kind. Miller mentions it as a distinct sort; some consider it the Welsh onion; and Milne thinks it may not improbably be the scallow leek, a species of Allium, grown in Pembroke-shire and other parts of South Wales, with roots in clusters like that of shallots. (Hort. Trans. iii. 416.)

3814. Estimate of sorts. The Strasburgh is most generally adopted for principal crops, and next the Deptford and globe. The Portuguese and Spanish yield large crops for early use, and the silver-skinned and two-blaided are reckoned the best for pickling. The potato-onion is planted in some places as an annual, but is considered inferior to the others in flavor: the Welsh onion is sometimes sown for early spring-drawing.

3815. Soil. The onion, "to attain a good size, requires rich meadow ground on a dry sub-soil. If the soil be heavy, it is best to confine it with a compost of fresh loam and well-composted dung, avoiding to use stable-dung in a rank unredced state. Turn the manure to a moderate depth; and in digging the ground, let it be broken fine. Grow picklers in poor light ground, to keep them small." The market-gardeners at Hexham sow their onion-seed on the same ground for twenty or more years in succession; non annually manure the soil, the manure, in a rotten state, is spread upon it, the onion-seed sown upon the manure, and covered with earth from the alleys, and the crops are abundant and excellent in quality. (Hort. Trans. i. 121.)
3816. Seed and times of sowing. When onions are to be drawn young, two ounces of seed will be requisite for a bed four feet by twenty-four; but when intended for full bulbing, one ounce will suffice for a bed five feet by twenty-four feet.

3817. The course of culture recommended by Abercrombie for the summer, and what he calls winter-standig onions; "Allot a bed thirty-six inches square, with a thin crop of grass, and divide it into five or six equal portions. Sow broad-cast, equally over the rough surface, moderately thick, bed and bed separately, and rake in the seed lightly on each bed, in a regular manner. When the plants are three or four inches high, in May and June, let them be timely cleared from weeds, and let the principal crop be thinned, either by cutting with a small two-toothed knife, or by thommers, leaving four or five inches between the plants in the main crops designed for full bulbing; or, some beds may remain moderately thick for drawing young, by successive thinnings, to the above distance. For the Spanish, from seed obtained immediately from the London nurserymen, or otherwise, take care to set them one to two inches asunder, or seven to eight inches asunder, for their young and advancing state. The plants will begin bulbing a little in June; more fully in July, and be wholly grown in August to full bulbs. In July or August, when the leaves begin to dry at the points and turn yellow, lay the stems down close to the bedding, bending them about two inches up the necks, when the tops will be divided into two or three parts or full bulbers will be ready to take up towards the middle of August. When the necks shrink, and the leaves decay, pull them wholly up in due time, spread them on a compartment of dry ground, in the five to six weeks, and the whole crop collected, and leaving them in dry air all night, they will be ready to house. Clear off the prosset part of the leaves, stalks, and fibres; then deposit the bulbs in some close dry apartment, in which sometimes turn them over, and pick out any that decay; and they will thus keep sound and good, all winter and spring, till May following."

3824. This Practice was recommended by Wordlidge in his Systema Horticulturae, published early in the 17th century, and has lately been revived by Knight, Warre, Macdonald, and others. It may be observed, that it has been practised, for an unknown period, in some of the market-gardens near London, known by the name of the "Gardens of the Neat's Houses." Knight observes, that the bulbous-rooted plant, and indeed every plant that lives longer than one year, generates in one season the sap or vegetable blood which comprises the leaves and roots of the succeeding spring. "This reserved sap is deposited, and, in some measure, the bulb; and the quantity accumulated, and stored up in the bulb, under the accumulated heat of the sun, generates in the arrangement and size of those thence imported. Seeds of the Spanish or Portugal onion are sown at the usual period in the spring, very thickly, and in poor soil; generally under the shade of a fruit-tree; and in such situations as are distant from the barnyard. One bulb only found, then taken from the ground, and preserved till the succeeding spring, when they are planted at equal distances from each other, and they afford plants which differ from those raised immediately from seed, only in possessing much greater vigor and stamina, owing to the quantity of previously generated sap being much greater in the bulbs than in the seeds. The size of the seed, and the diameter, length, and thickness of each inch in diameter, and being more mature, they are with more certainty, preserved in a state of perfect soundness, through the winter, than those raised from seed in a single season."

3825. The above method was found it perfect; and (Hort. Trans. iv. 123.) Brown, of Perth, has practised transplanted onions for upwards of twenty years; all the difference between his mode and that of Knight and the Neat's Houses' gardeners, is, that, instead of sowing under the shade of trees, he picks out all the small onions, from the size of a pea to that of a fibbert, from his general crop. If the small bulbs are of the same variety, they can be thinned out, and the remaining bulbs much greater in size than those which are grown directly from seed."

3826. James transplants either autumn-sown onions, or such as are forwarded by a hot-bed in spring, in drills which have been dunged, by which he considers a larger crop may be obtained with less dung than by the broad-cast mode of dunging. (Hort. Trans. iv. 123.)

3827. Warre states that the onion is also transplanted in Portugal, and the general practice is as follows: the seed is sown "very thinly, in November or December, on a moderate hot-bed, in a warm situation, with a few inches of rich light loam upon it, and the plants protected from frost by mats and hoops. In April, or whenever they are about the size of a large swan's quill, they are transplanted on a rich light loam, well manured with old rotten dung. The mode of transplanting is particular. The plants are laid flat, about nine inches asunder, each way, in quincuncx, the beard of the root, and part only of the plant, lightly covered with very rich mould, well mixed with two thirds of good old rotten dung. This compost is drawn moderately thine, and when the plants are then on the surface of the earth, there is given the second dressing of the same sort of dung, and being more mature, they are with more certainty, preserved in a state of perfect soundness, through the winter, than those raised from seed in a single season."

3828. Warre's practice was followed for upwards of twenty years; all the difference between his mode and that of Knight and the Neat's Houses' gardeners, is, that, instead of sowing under the shade of trees, he picks out all the small onions, from the size of a pea to that of a fibbert, from his general crop. If the small bulbs of the same variety, they can be thinned out, and the remaining bulbs much greater in size than those which are grown directly from seed.

3829. Macdonald's practice is noticed and approved of by Warre. "He sows in February, sometimes on a slight hot-bed, or merely under a glass frame; and between the beginning of April and the middle of July, or the beginning of June, he transplants the plants, in the heaviest, most tempestuous weather, and in the wettest, rainiest weather, and at the distance of four or five inches from each other in the row. The bulbs thus enjoying the great and well known advantages of having the surface-earth frequently stirred, swell to a much larger size than those transplanted; while in firmness and flavor they are certainly not inferior to foreign onions." (Caled. Hort. Mem. ii. 68.)

3830. Whatever plan of transplanting spring-sown onions may be adopted, care should be taken to keep the incipient bulb above ground; and in the case of planting autumn-formed bulbs in spring, they should be set as slightly and loosely as possible, otherwise, in neither case, will the bulbs attain a satisfactory magnitude.

3831. Culture of a winter-standing crop to be drawn foruse the succeeding spring. "Allot a soil rather heavy, but well manured, for your summer crop, on a sub-soil at least equally dry. The compartment, especially for any of the bulbous kinds it would lie more easy to raise, is about five feet wide, running parallel to the best aspect. The medium time for the principal sowing falls about the seventh of August; and for a secondary crop, near the 25th. Sow the bulbing sorts and the Welsh perennis, in three inches, carefully hand-weeded in time, before any rising weeds spread; not thinning the plants, being too thin, and leaving a less chance in winter, and to be by degrees drawn thinly for the winter; but reserve a principal portion for transplanting the onion, in particular, commonly dies down to the ground about mid-winter; but the root-part, remaining wholly sound, sends up a new vigorous shoot in February and March. For transplanting, let the whole of both sorts be well cleared from weeds; they will continue fit to draw young, during all the spring months, till May; then let some of the bulbous kinds be thinned. (Hort. Trans. ii. 68.)

3832. Whatever plan of transplanting spring-sown onions may be adopted, care should be taken to keep the incipient bulb above ground; and in the case of planting autumn-formed bulbs in spring, they should be set as slightly and loosely as possible, otherwise, in neither case, will the bulbs attain a satisfactory magnitude.
3825. **Lifting and preserving the general crop of onions.** This, according to Nicol, should not be delayed after the beginning of the middle of September. When taken up, they are to be spread thin on the ground; "but if the weather be wet, they had better be removed to a gravel walk, or a space purposely covered with sand or gravel, in the full sun. Turn them over once or twice a-day, until they are thoroughly dried, and then store them in a well aired loft, &c.; here still turn them occasionally, if they lie anywise thick; or may string them up by the tails, or hang them in nets. If they are not intended to be strung, the tails and outer husks should be displaced before housing them, and the latter at all events; that is, just as much as comes easily off in rubbing. The manner of stringing them is this: take in your hand three or four by the tails; tie the heads together by a new strand of matting, or a bit of picket-thread; place on two or three monofilament thread one or two rounds on the thread once or twice round their tails; place more string, or hang them up, which also lap hard, and so on. In this manner may be made a string (as it is called), or bunch, of a yard in length, or more; which by being hung up in a dry well aired place, free from frost, is an excellent way of keeping onions." In Portugal, "when the onions are ripe," Warren observes, "they are drawn up out of the ground, and a twist is given to the top, so as to bend it down. They are left on the ground to season, before they are housed; then, immediately platted with dry straw into ropes or strings, of twenty-five each, and hung up to dry; they are not permitted to sweat in a heap. Their keeping well depends greatly on the care and attention they are brought into the house, and also upon their being carefully handled, and not bruised. In this country, I have practised, with much success, searing the roots with a hot iron, for the purpose of preserving the onions, which checks their sprouting, and they should be kept in a dry airy place."

3826. **To save seed.** "Select some of the largest, well housed, sound, firm bulbs, either in October, the beginning of November, or in February. Draw drills three or four inches deep, either a single row, or two or three rows together, a foot asunder; in which plant the onions, six, ten, or twelve inches apart, and earth in about three inches. In planting double or treble rows, allow an interval of two feet between each bed of two or three rows, to admit of going in, both to place stakes and horizontal lines for the support of the seed-stems, and to cut down weeds. The plants will shoot up in stalks two or three feet high, producing each a large head of seed, which will ripen in August or September."

3827. **Culture of the potatoe-onion.** This variety, erroneously supposed to have been brought from Egypt by the British army about 1805, was grown in Driver's nursery in 1796, and has been known in Devonshire for upwards of twenty years. It is thus cultivated at Arundel Castle, by Maher. Having thoroughly prepared the ground, and formed it into beds four feet wide, "I draw lines the whole length, three to each bed, and with the end of the rake handle, make a mark (not a drill) on the surface; on this mark I place the onions, ten inches apart; I then cover them with leaf-mould, rotten dung, or any other light compost, just so that the crowns appear exposed. Nothing more is necessary to be done until they shoot up their tops; then, on a dry day, they are earthed up, like potatoes, and kept free from weeds until they are taken up. In the west of England, where this kind of onion is much cultivated, I understand that it is the practice to plant on the shortest day, and take up on the longest. The smallest onions used for planting swell, and become very fine and large, as well as yield offsets; the middle-sized and larger bulbs produce greater clusters." (Hort. Trans. iii. 305.)

3828. **Dymond states (Hort. Trans. iii. 306.), that in Devonshire it is planted in rows twelve inches apart, and six inches' distance in the row; that the plants are earthed up as they grow, and that the smaller bulbs yield a greater increase than the larger. A similar practice is adopted by some Scotch cultivators. (Caled. Hort. Mem. i. 343. and iv. 216.)

3829. **Wedgewood does not earth up, and finds his bulbs acquire a much larger size than when this practice is adopted.** (Hort. Trans. iii. 403.) The fact is, as we have observed in generalising on the subject of earthing up (8233.), surface-bulbs, as the onion, turnip, &c., are always prevented from attaining their full size by that operation, whatever they may gain in other respects.

**Subsect. 2. Leek.—Allium porrum, L. (Blackv. t. 491.) Hexan. Monog. L. and Asphodelacee, B. P. Poireau, Fr.; Lauch, Ger.; and Poro, Ital.**

3830. **The leek is a hardy biennial,** a native of Switzerland, and introduced in 1562. The stem rises three feet, and is leafy at bottom, the leaves an inch wide. The flowers appear in May, in close, very large balls, or purplish peduncles. The leek is mentioned by Tusser; but was, no doubt, known in this country long before his time. Worlidge, speaking of Wales, says, "I have seen the greater part of a garden there stored with leeks, and a part of the remainder with onions and garlic."

3831. **Uses.** The whole plant is used in soups and stews; but the blanched stem is most esteemed. Leeks formerly constituted an ingredient in the dish called porridge, which some suppose to be derived from the Latin porrum.

3832. **The varieties are—**

| The narrow-leaved, or Flanders leek | The Scotch, or flag, or Musselburgh | The broad-leaved, or tall London leek |

3833. **Propagation.** From seed; and for a bed, four feet wide by eight in length, one ounce is requisite.

3834. **Soil and site.** The soil should be light and rich, lying on a dry sub-soil. A rank soil does not suit it, so that when manure is necessary, well reduced dung, mixed with road-drift, is better than dung alone. The situation should be open. Let the ground be dug in the previous autumn or winter ready for sowing in spring. For the principal crop, allot beds four or five feet wide. A small crop may be sown
PRACTICE those and trim 3844. They permitting

ASPARAGINOUS

but while 643

the Rockenhollun, and sometimes a clove or two is put in winter salads. The roots become mature in July and August, and, dried and laid in store, are in season till the following spring.

3847. Culture. The shallot is propagated by dividing the clustered root into separate offsets. These are to be planted in February, or early in March, or in October and November. Planting in autumn is generally preferred as producing the best bulbs; but great care must be taken that much wet do not reach the roots in winter. Abercrombie directs to "lay out some light rich ground, in beds four feet wide, and in rows extending along these, to plant the offsets six inches apart, either in drills two inches deep, or inserted to that depth by the dibber, or with the finger and thumb." Nicol advises not to dund land intended for shallots, as rendering them liable to the attacks of maggots and insects: a very common complaint of gardeners.

3848. Machray, at Errol, (Cat. Hort. Mem. i. 275.) finds soil mixed with the manure given to shallot-beds effectual in preventing the appearance of maggots; while the roots were improved in size.

3849. Henderson, of Delvine, (Caled. Mem. vol i. 192.) to prevent the maggot, picks out the very smallest shallot-roots for planting; manures the ground with well rotted dung or house-ashes. He plants about the middle of October, as recommended by Marshal, and never has had the roots injured by the maggot in the smallest degree. "Autumn planting," he says, "is the whole secret." To prove this, he planted some roots in spring, only seven feet distance from those planted in autumn; and while the latter were untouched, the former were destroyed by these insects. The smallness of the roots planted, prevents them from growing mouldy. The most intense frost does not hurt them. From 204 clove planted in October, 1810, he lifted, in August, 1811, above 5000 good clean roots, measuring in general about three and a half inches in circumference.

3850. Knight, to guard against the maggots in shallots, tried planting the bulb on the surface, instead of burying it two or three inches in the soil; and the experiment was attended with such perfect success, that he confidently recommends this mode of culture. He places a rich soil beneath the roots, and raises the mould up each side to support them till they become firmly rooted. This mould is then removed by the hoe and water from the rose of a watering-pot, and the bulbs, in consequence, are placed wholly out of the ground. "The growth of these plants," he adds, "now so close resembled that of the common onion, as not to be readily distinguished from it; till the irregularity of form, resulting from the numerous germs within each bulb, became conspicuous. The forms of the bulbs, however, remained permanently different from all I had ever seen of the same species, being much more broad and less long; and the crop was so much better in quality, as well as much more abundant, that I can confidently recommend the practice of culture adopted to every gardener." (Hort. Trans. 1822. ii. p. 88.)

3851. Taking and preserving the crop. When the leaves begin to decay, the bulbs are fit to be taken up, when they should be dried and housed, either on the floor of the root-loft, in nets hung from the roof, or in strings, as recommended for onions. Should any roots be wanted during the growth of the crop, a few may be taken up young in June and July for immediate consumption.

Subsect. 6. Rocambole. — Allium Scorodoprasum, L. (Pench. t. 256.) Hexan. Monog. L. and Asphodeleae, B. P. Ail d'Espagne, Fr.; Rockenbollan, Ger.; and Scorodopraso, It. 3852. The rocambole is a perennial plant, a native of Denmark, and mentioned by Gerrard as cultivated in 1596. It has compound bulbs, like garlic, but the cloves are smaller. These are produced at the roots, and also, though of a smaller size, on the stem, which rises two feet high, and produces the bulbs in the axilie of the leaves in July and August.

3853. Use. The cloves, both of the stalk and root, are used in the manner of garlic or shallot, and nearly for the same purposes. It is considered milder than garlic.

3854. Culture. It is propagated by planting the separated cloves of the root-bulb, or occasionally the cloves of shallots. A small plot is ample, but few rows will be sufficient for a family garden. Plant it either by dibble, or in drills, in rows six inches apart, and two inches deep. The plants shoot up, each in a slender stalk, contorted at top, and terminated by a small head of cloves, which, as well as the root, will acquire full growth in July or August, for immediate use; or to be taken up, and spread to dry, tied in bunches, and housed for future consumption.

Sect. VI. Asparagus Plants.

3855. The asparagus class of esculents may be considered as comparatively one of luxury. It occupies a large proportion of the gentleman's garden, often an eighth part; but does not enter into that of the cottager. A moist atmosphere is congenial to the chief of them, especially to asparagus and sea-kale, which are sea-shore plants, and are brought to greater perfection in our islands than anywhere else, excepting perhaps in Holland.

Subsect. 1. Asparagus. — Asparagus officinalis, L. (Eng. Bot. t. 339.) Hex. Monog. L. and Asphodeleae, B. P. Asperge, Fr.; Spargel, Ger; and Asparagus, It. 3856. The asparagus is a perennial plant, found in stony or gravelly situations near the sea, but not very common. It grows near Bristol, in the Isle of Portland, and sparingly in Seaton Links, near Edinburgh. The roots consist of many succulent round knobs, forming together a kind of tuber, from which numerous erect round stems arise with alternate branches, subdivided into alternate twigs, not unlike a larch fir-tree in miniature. The leaves are very small, linear, and bristle-shaped; the flowers nodding, of a yellowish-green, and odorous, are produced from June to August; and the berries of a yellowish-red: the whole plant has a very elegant appearance. Many of the stepps in the south of Russia and Poland are covered with this plant, which

T t 2
is there eaten by the horses and oxen as grass. In its native state, it is so dwarfish in appearance, even when in flower, that none but a botanist attending to the minute structure, would consider it as the same species with our cultivated plant. This vegetable is cultivated extensively for the London market; and it is estimated, that in the parish of Mortlake alone, there are generally about eighty acres under this crop. One grower there, Biggs, has sometimes had forty acres under asparagus at one time. A great deal is also grown near Deptford, and one grower there, Edmonds, has had eighty acres entirely under this crop; — a thing, Neil observes, which must appear almost incredible to those who have not witnessed the loads of this article daily heaped on the green-stalls of the metropolis for the space of nearly three months. Asparagus, this author adds, was a favorite of the Romans; and they seem to have possessed a very strong-growing variety, as Pliny mentions, that, about Ravenna, three shoots would weigh a pound; with us, six of the largest would be required. It is much praised by Cato; and as he enlarges on the mode of culture, it seems probable that the plant had but newly come into use. In this country, Dutch asparagus was preferred in the end of the 17th century; and this variety is still distinguished for affording the thickest shoots. In a garden formed at Dunbar, in the very beginning of the 18th century, by provost Fall (a name well known in the mercantile world), asparagus was for many years cultivated with uncommon success. The variety used was the red-topped, and it was brought from Holland. The soil of the garden is little better than sea-sand. This was trenched two feet deep, and a thick layer of sea-weed was put in the bottom of the trench, and well pressed together and beat down. This was the only manure used, either at the first planting, or at subsequent dressings. There was an inexhaustible supply of the article generally at hand, as the back-door of the garden opens to the sea-shore. (Ed. Encyc. art. Hort.)

3857. Use. The esculent part is the early shoots or buds, when three or four inches high, and partially emerged from the ground in May and June. They are in great esteem in Britain, and on the continent; and this plant has, in consequence, been cultivated for an unknown period. In Paris it is much resorted to by the sedentary operative classes, when they are troubled with symptoms of gravel or stone.

3858. Varieties. There are two varieties cultivated: viz.

The red-topped; rising with a large head, fall, close, and of a reddish-green
The green-topped; rising with a smaller head, not generally so plump and close, but reckoned better flavored

The Battersea, Deptford, Large Gravesend, Large Reading, Dutch, Cork, and Early Mortlake are sub-varieties.

3859. Estimate of sorts. Both varieties are in great estimation: the red-topped is most generally cultivated by market-gardeners, and the green-topped in private gardens. Both succeed by the same mode of culture.

3860. Propagation. Asparagus is propagated only from seed, though the roots might be divided like those of the garden-ranunculus, if thought necessary. It is best, however, to raise the plant from seed; and it is of considerable importance to gather it from the strongest and most compact shoots; such seed, as might naturally be expected, yielding by far the best plants. Seed, as well as one and two year-old plants, may be purchased from nurserymen and market-gardeners: and when a new garden is formed, the latter practice is generally adopted for the first plantation, in order to gain time.

3861. Quantity of seed or roots. If sown to transplant, for a bed four feet and a half wide by six feet in length, one quart of seed will be requisite. If sown to remain, for a bed four feet and a half wide by thirty feet in length, one pint is necessary. If plants a year old are wanted for a plantation, then, for a bed four feet and a half wide by thirty feet in length, to contain four rows of plants, nine inches distant in the row, one hundred and sixty plants will be requisite.

3862. Sowing, and culture in seed-bed. It is generally sown broad-cast on a four-feet bed, in March, not very thickly, often with a thin sprinkling of onions or radishes. The seed being slightly trodden in, the bed is raked smooth, and after the plants make their appearance, they are to be kept as free from weeds as possible, and the ground stirred with a narrow hoe once or twice during the summer. In the end of October following, the roots are protected from the frost by spreading over the ground some rotten dung or litter, which remains till March or April, according to the season, when the plants are transplanted to a compartment prepared for their final culture.

3863. Jedd (Hort. Trans. vol. ii.) sows in drills eighteen inches apart, burying the seed two inches: the object is to admit of stirring between. He keeps the plants thin, and if the weather prove dry, waters once a week or fortnight.

3864. Soil and preparation. "Asparagus-ground should be light, yet rich; a sandy loam, well mixed with rotten-dung or sea-weed, is accounted preferable to any. The soil should not be less than two feet and a half deep; and before planting a bed, it is considered good practice to trench it over to that depth, burying plenty of dung in the bottom, as no more can be applied there for eight or ten years. It can scarcely, therefore, be too well dunged; besides, although the plant naturally grows in poor sandy soil, it is found that the sweetness and tenderness of the shoots depend very much on the
rapidity of the growth, and this is promoted by the richness of the soil. Damp ground, or a wet sub-soil, are not fit for asparagus: indeed, the French consider wetness as so prejudicial to this plant, that they raise their asparagus-beds about a foot above the alleys in order to throw off the rain."

(Neill.)

3865 Abercrombie says, "For planting asparagus, allot a plot of sound brownish loam, mixed with sand, in an open compartment, full to the sun. Having trenched it thirty inches deep, or as near that depth as the soil will allow, manure the bed with well reduced dung, six inches thick, or more, digging in the manure thoroughly, and the ground as for beds for lettuces. Make the ground for the bed firm and level, with intervening alleys three feet wide. If the soil is naturally too light and poor, improve it with a little vegetable mould, or pulverised alluvial compost, after the bottom has been dunged."

3866 This is the method, as stated in the Horticultural Society, in 1815, "a specimen of asparagus, pronounced, by those who saw it, to be the finest they had ever seen," says, "Prepare a piece of good land, unencumbered with trees, and that lies well for the sun; give it a good dressing of well reduced horse-dung from six to ten inches thick, all regularly spread over the surface; then proceed with the trenching (if the soil will admit) two feet deep; after this first trenching, it should lie about a fortnight or three weeks, and then be turned back again, and then again in the same space of time; by this process, the dung and mould would become well incorporated; it may then be laid in small ridges till the time of planting. This work should all be performed in the best weather the winter will afford, that is, not while it rains, or snow is lying on the ground, as it would tend to make the land heavy and sour; all this is to be particularly attended to, as the preparation of the soil is of more consequence than all the management afterwards. At the time of planting, I always spread over the ground another thin coat of very rotten dung, and plant it in half a spade deep, making my beds three feet only, with two feet of alleys; so that the rows of grass, one foot apart, are all 1 plant on each bed: I find this to be the best method, as by this plan there is not the least trouble in gathering, whereas you are obliged to set a foot on one of the wide beds, before you can get at all the grass, to the great injury of the bed and the buds under the surface."

3867 Asparagus is a very rapid grower, and the first plantings, which are made in the month of April, are prepared for beds in France; and which, it is stated, has been adopted by a gentleman in Peeblesshire with success. "A pit, the size of the intended plantation, is dug five feet in depth, and the mould which is taken from it, must be sifted, taking care not to reject any fibres, even the root of asparagus bed, as it is a fibrous sand as the mould must then be laid aside for making up the beds. The materials of the bed are then to be laid in the following proportions and order: six inches of common dunghill-manure, eight inches of turf, six inches of dung as before, six inches of sifted earth, eight inches of turf, six inches of very rotten dung, eight inches of the best earth. The last layer of earth must then be well mixed with the last of dung. The compartment must now be divided into beds five feet wide, by paths constructed of turf, two feet in breadth, and one foot in thickness."

(Caled. Hort. Mem. vol. ii.)

3868 One of the best descriptions of the Vienna mode of making an asparagus-bed to last 25 years. It is deeply trenched, and in the bottom is placed a layer of bone, horn, chips of wood, or branches of trees a foot thick. Over this is placed good mould, cow-dung, and river mud, &c. (Hort. Trans. v. 333.)

3869 Removal and planting. Take up the plants carefully with a fork, to avoid cutting the roots, exposing them to the air as short a time as possible; and at the time of planting, place them among a little sand in a basket covered with a mat. Nicols says, "It is of very great importance for the ensuring of success in the planting of asparagus, to lift the roots carefully, and to expose them to the air as short time as possible. No plant feels a hurt in the root more keenly than asparagus; the fibres are very brittle, and if broken, do not readily grow again."

(Kal. 47.)

3870 Smith proves experimentally, that though the common season for planting is March and April, yet, that it may also be successfully performed in June, without any extraordinary care. Judd, already mentioned, transplants when he observes the plants beginning to grow, which, he says, is the best time for the plants to succeed. If moved earlier, they perhaps have to be torpid for two or three weeks, which causes many of the shoots to wither. If moved too late (after the sun has dried the plant places) the plants may even as late as July, cutting off such young shoots as the plants have made before the operation. (Caled. Hort. Mem. vol. i.)

3871 Distance at which asparagus is commonly planted is nine inches in the row, and one foot between the rows; in general, between every fourth row so planted, a double distance is left for an alley. Many asparagus-farmers, however, consider it better to plant in single rows at two feet and a half or three feet distance, than to adopt the bed form. The crowns of the plants are generally covered two inches with soil.

3872 Method of planting. "Stretch a line lengthwise the bed, nine inches from the edge, and with a spade, cut out a small trench about six inches deep, perpendicular next to the line, turning the earth displaced along by the other side the trench; and, having the plants ready, set a row along the trench, nine inches apart, with the crown of the roots two inches below the surface, drawing some earth just to fix them as placed. Having planted one row, directly cover them in with fully with the earth of the trench, raking it back regularly an equal depth over the crown of the plants. Proceed then to open another trench a foot from the first; plant it as above; and in the same manner plant four rows in each bed. Then lightly raking the beds lengthwise, draw off any stones and hard clods, and dress the surface near and even. Then let the edges be lined out in exact order, allowing three feet for each alley. But sometimes in planting large compartments of asparagus, a first trench having been made, and the roots planted as above, then a second trench is opened, of which the earth is turned into the first over the plants. So proceed in planting the whole; making allowance between every four rows for an alley of three feet. In a dry spring or summer, water the roots from time to time, till the plants are established." (Abercrombie.)

3873. Smith strains the line, and cuts down a trench, sloping in the usual way for planting box, and making choice of all the finest plants, puts them in one foot apart, and one inch and a half below the surface. This done, he lets the alleys and beds lie level till autumn, and then digs out the alleys deep enough to get the roots and shoots to six inches of mould all over the bed; over this he lays a good coat of rotten dung, and fills in the alleys with long dung.

3874. In France, they plant in beds five feet wide, separated by paths constructed of turf, two feet in breadth, and one foot in thickness. The plants are placed eighteen inches asunder, spreading out the roots as wide as possible in the form of an umbrella, and keeping the crown one and a half inch under ground.
A pin is put to each plant as a mark; and as soon as the earth is settled and dry, a spadelike of fine sand is thrown over each pin in the form of a mole-hill.

3876. Extent of the plantation. An asparagus-compartment should not contain less than a pole of ground, as it often needs this quantity to furnish a good dish at one time. For a large family, about sixteen roods are kept in a productive state, which are calculated to furnish, on an average, between two hundred and three hundred shoots every day in the height of the season. (Neill, in Ed. Encyc.)

3877. Abercrombie says, when the buds come to be fully productive, five square poles of ground, planted with 1600 plants, will yield from six to eight score heads daily.

3878. Progressive culture. Permit the entire crop the two first years, and the greater part of it the third year, to run up to stalks; keeping the beds free from weeds, and stirring the surface. It is a common practice to sow onions, lettuce, &c. the two first years over the beds; and to plant cauliflower in the alleys between them. The advantage of this practice is questionable; and, at all events, it should not be continued after the plants are in full bearing. Judd, having dug out the alleys the first season, instead of repeating that operation the next, lays on a coat of good dung three inches thick, and forks it evenly into the beds and alleys, and so on every season after, "never digging out the alleys any more, as it is known the asparagus-plant forms a fresh crown every season; and sometimes it happens, that in a few years the crown will increase almost into the alley; so, that by digging out this, you must inevitably spoil that plant: if this is not the case when the beds are in good condition, the roots will be sure to work out at the sides into the alleys, and by digging out the latter, these roots must be cut off, and you will often see them exposed all the winter before dung can be got to fill them up; rather than be treated in this way, they had better be without any thing all the winter, as asparagus does not suffer generally by frost. The first two years I have a very thin crop of celery-plants or lettuce upon the beds, but nothing afterwards; nor do I plant any thing in the alleys after the same period, for I think the asparagus is injuried thereby."

3879. Autumn dressing. The following is the usual practice, as described by Abercrombie: "Towards the end of October or beginning of November, the stalks which have run up to seed, having done growing, or begun to decay, cut them down close, and carry them away; then hoe off all weeds from the beds into the alleys: this done, proceed with the line and spade to mark out the alleys the prescribed width; then dig each alley lengthwise, a moderate spade deep, and spread a good portion of the earth equally on each side over the adjoining beds; digging down the weeds as you advance, clean to the bottom of the alleys, under a proper depth of earth. Form the edges of the beds full and straight, and the alleys of an equal depth; and thus let them remain till spring."

3880. Judd, on the above practice, observes, "rather than treat them in this way, they would be better without any thing." He fills up the alleys with litter or dung, to exclude the frost.

3881. Nicol recommends covering asparagus-beds with good dung, and not mere litter, as frequently is done, in the idea that the roots would otherwise perish. Fresh dung mixed with sea-weed, he considers the very best manure for asparagus. (Kal. 193.)

3882. The French cover in autumn, with six inches of dung, and four of sand; and in performing this operation, as well as every other, great care is taken not to tread on the beds, so as to condense the earth. In planting and cutting, a plank is always used to tread on; and the turf-divisions of the beds which are intended to prevent the condensation of the earth below, in consequence of walking among the beds, are removed every three years.

3883. Neill mentions a very proper precaution before covering, which is, to stir the surface of the beds with a fork, in order that the juices of the manure washed down by the rains, may be readily imbribed. He adds, that some cover the manure with a thin layer of earth from the alleys, which is called landing up.

3884. Spring dressing. About the end of March or towards the middle of April, before the buds begin to advance below, proceed, with a short three-tined fork, to loosen the surface of the beds; introducing the fork slanting two or three inches under the mould, turn up the top earth near the crown of the roots, with care not to wound them. Then rake the surface lengthwise the bed, neatly level, drawing off the rough earth and hard clods into the alleys; also, trim the edges of the beds and surface of the alleys regularly even. Thus to loosen the bed, enables the shoots to rise in free growth, admits the air, rains, and sunshine, into the ground, and encourages the roots to produce buds of a handsome full size. (Abercrombie.)

3885. Time of coming to a bearing state. In general, transplanted asparagus comes up but slender the first year; it is larger the second; and the third year some shoots may be fit for gathering; in the fourth year the crop will be in good perfection. (Abercrombie.)

3886. Judd begins to cut the third season, but not generally. By the French method before mentioned, "in three years the largest plants will be fit to cut for use."

3887. Blanching. No attempt at blanching the tops is made in this country, otherwise than by having abundance of loose earth on the surface through which they spring; but Lasteyrie informs us (Col. de Machines, &c.) that joints of cane are placed separately over each stalk in Spain; and Bauman of Vienna, in a communication to the Horticultural
Society on the culture of asparagus in Austria, says, "to give asparagus-shoots growing in the open air as much length and tenderness as possible, there is inserted over each stem destined to be gathered, as soon as it shoots above ground, a woolen tube or pipe eighteen inches high, and one inch in diameter." (Hort. Trans. v. 334.) Dr. Forbes, on the same subject, says, "in order to preserve the whiteness of the asparagus-shoots, they should be covered with a wooden or earthen pipe of twelve or fifteen inches in height, with a hole in the top." (Hort. Trans. v. 336.)

3888. Cutting and gathering. "In new plantations, be careful not to begin cutting till the stools are advanced to mature age, having been planted three or four years, and become of competent strength for producing full-sized shoots. Likewise observe, both in new and old beds, to gather all the produce in a regular successive order within the proper limits of the season specified above. As the rising shoots project two, three, four, or five inches at most above ground, while the top bud remains close and plump, they are in the best condition for gathering. Cut them off within the ground, with a narrow sharp-pointed knife, or small saw, nine inches long; thrusting the knife, or saw, down straight, close to each shoot separately, cut it off slantingly, about three inches below the surface, with care not to wound the younger buds advancing below. Observe, in a new plantation, in the first year's gathering, if the shoots come up of irregular sizes, to cut only some of the larger for a fortnight, or three or four weeks, and then permit the whole to run; but otherwise, when in strong production, gather all as they come, two or three times a-week, or as required, during the season, till the 21st of June; then, at farthest, terminate the cutting, and permit the after-shoots to run up in stalk till October. If from a particular inducement you cut later than the 21st of June, be careful to leave two or more shoots to each stool, in order to draw nourishment to it; for the stools left without growing shoots will perish, and by negligence in this respect many vacancies or unproductive spots are left in beds." (Abercrombie.)

3889. Nicol says, the best method of cutting is to scrape away an inch or two of the earth from the shoot you would cut, and then slip the asparagus-knife (figs. 111, 112) down another inch or two, taking care not to wound the crown, or any adjoining shoot. Shoots two inches under the ground, and three or four above it, make the handsomest dishes.

3890. NeilI observes, "after the beds are in full bearing, all the shoots are gathered as they advance, till the end of June or beginning of July; a common rule being to "let asparagus spin (grow up), when green peas come in." Dr. Macculloch states that the same practice is pursued in France.

3891. Judd says, "I never make a practice of cutting very much after the first week in June: I then begin to let it run; in fact, I never cut the very small grass at all. Asparagus being so valuable a vegetable, some persons continue to cut indiscriminately till the latter end of June, but this practice is of very great injury to the next year's produce." (Hort. Trans. vol. ii. 237.)

3892. Duration of the crop. Generally, three months; from the middle of April to the middle of July. (NeilI.)

3893. Duration of the plantation. Abercrombie says, "A plantation of asparagus, under good culture will mostly continue for ten or twelve years to afford plentiful crops; after which, the stools usually decline in fertility, and the shoots in quality; so that to provide a permanent annual supply, some fresh beds should be planted a sufficient time beforehand, allowing four years for their advancing to a productive state."

3894. Dr. Macculloch says, the French beds which he describes "will generally last thirty years; but, if they be planted in such abundance as to require cutting once in two years, half the bed being always in a state of reservation, it will last a century or more." (Calcd. Mem. vol. ii. 250.)

3895. To save asparagus-seed. "Select some of the finest and earliest heads as they make their appearance in the spring; tie them to stakes during summer, taking care not to drive the stake through the crown of the plant. In autumn, when the berries are ripe, wash out the seeds, if for the market, or to be sent to a distance; but, for home-sowing, keep them in the berry till the time of sowing, the pulp being a great nourishment to the seed, which ought to be kept in a dry place during the winter." (Judd, in Hort. Trans. vol. ii. 234.)

3896. Forcing asparagus. Meager, writing in the middle of the 17th century, mentions, that the London market was, at that period, supplied with forced asparagus early in the year. "Some having old beds of asparagus, which they are minded to destroy, and having convenience of new or warm dung, lay their old plants in order on the dung, and the heat doth force forward a farewell crop." (English Gardener, 188.) Where much asparagus is forced, it becomes necessary to form plantations on purpose for an annual supply. The plants are raised from seed in the usual way; but when transplanted, as they are not intended to remain longer than three years in the bed or plantation, they need not be planted wider than seven or nine inches. When of three years' standing in the bed, they are eligible for removal to the forcing pit or frame, or to be excited by a superstratum of man and warm dung, in the manner of sea-kale or rhubarb. As some guide to proportion the forcing plantations to the demand, 600 plants are required for an ordinary-sized three-light frame, which, Nicol says, will yield a dish every day for about three weeks.

3897. For the details of forcing asparagus, see Ch. VIII. Sect. IX.

3898. The sea-kale is a hardy perennial, found in various parts of our shores. The whole plant is smooth, of a beautiful glaucous hue, covered with a very fine meal; occasionally, however, it varies like the wallflower-leaved ten-week stock, with quite green leaves. The radical leaves are large, more or less sinuate and indented, containing in the axil a bud or rudiment of next year's stem. The flower is of a rich white appearance, and smells strongly of honey. The common people on the western shores of England have, from time immemorial, been in the practice of watching when the shoots begin to push up the sand or gravel, in March and April; when they cut off the young shoots and leaf-stalks, then blanched and tender, and boil them as greens. The precise period of its introduction to the garden is unknown. Parkinson and Bryant state, that the radical leaves are cut by the "inhabitants where the plant grows wild," and boiled as cabbage; and Jones, of Chelsea, assured the late Curtis, that he saw bundles of it, in a cultivated state, exposed for sale in Chichester market in 1753. Maher states (Hort. Trans. 1.), that the crambe maritima was known and sent from this kingdom to the continent more than two hundred years ago, by Lobel and Turner; but Miller, in 1731, was the first who wrote upon it professionally. About the year 1767, it was cultivated by Dr. Lettsom, at Grove Hill, and by him brought into general notice in the neighborhood of London. In the Gardener's Dictionary, published in 1774, by Gordon, at Fountain-bridge, near Edinburgh, directions are given for the cultivation of this vegetable, and for blanching it, by covering the beds four inches deep with sand or gravel. Professor Martyn has printed some valuable instructions for its cultivation, from the MS. of the Rev. M. Laurent; and the late Curtis, by a pamphlet on its culture, has done more to recommend it, and diffuse the knowledge of it, than any of his predecessors. Sea-kale is now a common vegetable in Covent Garden market, and Nell observes, has even begun to appear on the green-stalls of the Scottish metropolis. But in France it is nearly unknown. Bastien (Manuel du Jardindier, 1807) describes the chou marin d'Angleterre, but he appears to have tried to use the broad green leaves, instead of the blanched shoots. Disgusted with his preparation, he denies the merits of sea-kale; and resigns the plant, with a sneer, to colder climates. When the French gardeners, however, have learned to cultivate it, and especially to force it at mid-winter, it will doubtless soon become a favorite with the Parisians. (Ed. Encyc. art. Hort.)

3899. Use. The young spring shoots, and the stalks of the unfolding leaves, blanched by rising through the natural ground in a wild state, or by earthing up in gardens, are the parts used; and when boiled, and dressed as asparagus, are not inferior to that vegetable. They form also an excellent natural ingredient in soups. Sometimes the ribs of the large leaves are peeled and dressed as asparagus, after the plant has ceased to send up young growths. By forcing, sea-kale may be had in perfection from November till May, a period including all the dead months of the year. It is remarked by Nicol, that vegetables are seldom improved by forcing, but that sea-kale forms an exception, the forced shoots produced at mid-winter being more crisp and delicate in flavor than those procured in the natural way in April or May. Sir George Mackenzie (Caled. Hort. Mem. vol. i. 313.) observes, that sea-kale cannot easily be overdone in cooking, and that after being well boiled, it should be thoroughly drained, and then suffered to remain a few minutes before the fire, that a farther portion of moisture may be exhaled.

3900. Propagation. Sea-kale is generally and best raised from seed; of which, if sown to transplant, for a seed-bed four feet by nine, sown in drills a foot apart by eight inches in the row, two ounces will suffice; if sown to remain, then the same quantity will serve for a plot five feet by fifteen, sown in drills two feet apart. Plantations may also be formed by detaching rooted offsets from established plants, or by cuttings of the roots, leaving about two eyes to each cutting. The last fortnight of March, and the first of April comprises the best time for putting in seed, or cuttings, and removing plants.

3901. Soil. The native soil of sea-kale is deep sand, sometimes covered or partially interlaminated with alluvial matter from the sea. "Hence," says Abercrombie, "a light, dry, moderately rich mould, of a loose texture, suits it best. A fit soil for it," he adds, "may be composed of one half drift sand, two sixths rich loam, and one third small gravel, road-stuff, or sea-coal ashes. If the loam be not rich, add a little rotten dung." Barton (Caled. Hort. Mem. vol. ii. p. 99.) cultivates sea-kale in "a pretty strong loam, on a loose till-bottom, which he previously prepared by trenching, and mixing with it a good portion of vegetable mould from decayed leaves, adding a quantity of river sand."

3902. Culture. Maher pursues the following mode: "Prepare the ground in December or January, by trenching it two feet and a half deep; if not that depth naturally,
and light, it must be made so artificially by adding a due proportion of fine white sand, and very rotten vegetable mould; if your ground is wet in winter, it must be effectually drained, so that no water may stand within a foot at least of the bottom; for the strength of your plants depends on the dryness of the bottom, and richness of your soil. Then divide the ground into beds, four feet wide, with alleys of eighteen inches, after which at the distance of every two feet each way, sow five or six seeds two inches deep, in a circle of about four inches in diameter: this operation must be performed with strict care and regularity, as the plants are afterwards to be covered with blanching-pots, and both the health and beauty of the crop depend upon their standing at equal distances.

In the months of May and June, if the seeds are sound, the young plants will appear. When they have made three or four leaves, take away all but three of the best plants from each circle, planting out those you pull up (which by a careful hand may be drawn with all their tap-root,) in a spare bed for extra forcing, or to repair accidents. The turnip-fly and wire-worm are great enemies to the whole class of tetradynamia plants. I know no remedy for the latter, but picking them out of the ground by hand; the former may be prevented from doing much damage, by a circle of quick-lime strewed round the young plants. If the months of June and July prove dry, water the whole beds plentifully. In the following November, as soon as the leaves are decayed, clear them away, and cover the beds an inch thick with fresh light earth and sand, that has lain in a heap and been turned over at least three times the preceding summer; this, and indeed all comports, should be kept scrupulously free from weeds, many of which nourish insects, and the compost is too often filled with their eggs and grubs. Upon this dressing of sandy loam, throw about six inches in depth of light stable-litter, which finishes everything to be done the first year. In the spring of the second year, when the plants are beginning to push, rake off the stable-litter, digging a little of the most rotten into the alleys, and add another inch in depth of fresh loam and sand. Abstain from cutting this year, though some of the plants will probably rise very strongly, treating the beds the succeeding winter exactly as before. The third season, a little before the plants begin to stir, rake off the winter covering, laying on now an inch in depth of pure dry sand or fine gravel. Then cover each parcel with one of the blanching-pots, pressing it very firmly into the ground, so as to exclude all light and air; for the color and flavor of the sea-kale is greatly injured by being exposed to either."

3905. Barton, in the autumn, covers all the sea-kale beds, excepting the roots intended to be taken up for forcing, with leaves, as they are raked up from the pleasure-grounds; covering each bed in thickness according to the strength and age of the roots, giving the greatest covering to the oldest, upon an average from five inches to a foot when first laid on: over this, I place a slight covering of long dung, just sufficient to keep the leaves from being blown about. The covering is suffered to remain on the beds until the whole is cut for use the following spring; after which the dung and leaves may be removed, and the ground dug regularly over. By this treatment, the heads will be found free and well blanched, and, from the sweetness of the leaves, free from any unpleasant flavor. As the heads become ready for use, they will raise the covering, by which means they will be easily perceived, without removing any more of the covering than is necessary. If the leaves are intended for forcing, they are cut, and those that are left, the thickest covering of leaves in autumn, come first into use, and the others in rotation; so that the last cutting is from what was sown the spring before. Aware that cutting from one-year-old plants is generally disapproved of, Barton defends the practice from his experience of its not proving injurious, and because thereby the sea-kale season is prolonged, as the one-year-old plants "come in much later in spring than the old-established roots." (Calce. Hort. Mem.)

3904. Taking the crop. Cut the young stems, when about three inches above ground, carefully, so as not to injure any of the remaining buds below, some of which will immediately begin to swell. A succession of gatherings may be continued for the space of six weeks, after which period the plants should be uncovered, and their leaves suffered to grow, that they may acquire and return nutriment to the root for the next year's buds. The flowers, when seeds are not wanted, ought to be nipped off with the finger and thumb, as long as they appear. (Hort. Trans. vol. i.)

3905. Forcing sea-kale. No vegetable is more easily or more cheaply forced than sea-kale, whether the operation be performed in beds or drills in the open air, or in hot-bed frames or flamed pits.

3906. Abercrombie, Nicol, and Maher recommend forcing in beds in the open air. "Seven weeks," the latter observes, "before the time at which you wish to cut shoots for the table, begin to prepare the plants for forcing, and to ferment a sufficient quantity of fresh stable-dung. Having trimmed the leaves from the plants, carefully point the surface of the ground; and over the tops of the roots, spread fresh light earth, mixed with drift-sand or coal-ashes, two or three inches in depth. When the dung is well manured, and in a proper state, and proceed in about a week. If the dung, when put on, is too hot, do not allow it to remain long on the dung, begin to ferment them a week or a fortnight sooner. Cover each of the plants, either with a regular blanching-pot, or with a garden-pot of the largest size. When the latter is employed, stop the holes of the side air tubes, cut off both the weather and the rank stalk of the lining. Then lay a portion of prepared dung alone or mixed with tree-leaves, about and over each pot, pressing it down firm, extending it eight or ten inches all round, and raising the bank six or eight inches above the pot. It will be necessary to examine the plants frequently, and to measure the heat within the chamber, by which means, the quantity of litter should not have been well-apportioned, or rightly prepared. If the heat be under 50°, there is not enough heat to excite the plants; and if above 60°, it is too fiery and may injure them. In about three weeks or a month after being covered up, the first shoots will be from six to ten inches long, and fit for the table. If the plant send up a flower-stalk, cut it away; and successive supplies of shoots will be produced, till perhaps the end of the third month from beginning to force."
3007. Maker observes, that the only thing necessary in forcing sea-kale, is to be very particular in guarding against too much heat, using trial-sticks, and never if possible, exceeding 55°. So much mischief ensues when this is violent, that it is far better to begin time enough, and force slowly, rather than quickly. This is particularly applicable to the forcing of sea-sea-kale sauces, sliced and tinned, which with dairy, small and very large. These are the best remedies against worms, which, after forcing is commenced, often spring up on the surface, and spoil the delicacy of the young shoots. Salt, he adds, also effectually destroys worms, and will also injure the sea-kale.

3008. Inconceivable says, unless the weather be unusually rigorous, it will not be necessary to renew the linings of hot litter oftener than once in seven or eight weeks. Take away the exhausted part, and mix the remainder with fresh dung and leaves. Maker says, after the sea-kale is gathered, the dung will be found in the finest possible state for spring hot-beds. When the stools will produce nothing more shoots, remove the litter and the covers, and dress the ground, in order, as observed by Maker, that their leaves may be suffered to grow, and acquire and return nutrient to the root, for the next year's buds.

3009. Nicol says, he knows an instance of a row of sea-kale having been forced in the above way every season for seven years, in which the plants in it are as vigorous and healthy as others in the same compartment that are forced only every second year.

3010. Barton forces sea-kale on dung-beds, under frames, exactly in the manner generally adopted for asparagus, but he considers the gravel to be the most useful if there be any of it at any particular time, and the saving of dung and labor. The latter saving, he says, "must appear obvious to every practical gardener, when he considers the difficulty attending the keeping up a proper and regular degree of heat, by covering with dung over pots and other similar methods, (as generally practised,) at so inclement a season of the year; requiring three times the quantity of dung to produce an equal number of heads, to what will be necessary when the roots are placed in a frame; for a common melon-frame will contain as many heads as are capable of being produced in two drills of twenty yards each, by covering with hot dung. He finds two frames, of three lights each, quite sufficient for a large family; the first prepared about the beginning of November, and the second about the last week in December; and by the time the second frame is exhausted, sea-kale will be ready for use in the open ground." (Caled. Hort. Mem.)

3011. McDonald, of Inverness, (Caled. Mem. vol. i. p. 338,) also forces in frames, blanching by keeping the bed covered with mats. Economy and certainty he considers to be the advantages attending this mode. As the plants are no longer of use after being forced, a succession is kept up by annual sowings, and the plants are allowed to attain three years' growth before taking it up for forcing.

3012. Maitland forces sea-kale where it stands in the open garden in the following manner: "On each side of a three-feet bed, in which the sea-kale has been planted, trenches are formed two feet deep, and eighteen inches wide at bottom; the side of the trench next the bed is perpendicular, and the other side is sloped, so as to make the top of the trench, at the surface-level, two feet and a half wide. The trench is filled with linings of hot dung, on the inner edges of which, garden-lights are placed, and the glass covered with mats until the kale is fit to cut. The same plan," he adds, "is applicable to asparagus, and also to rhubarb, or any other perennial vegetable intended to be excited where it stands, and a covering of beards, canvas, or matting, substituted for the glass lights." (Hort. Trans. iv. 63.)

3013. Metros, of Argowlan, forces sea-kale in a vineyard. He plants along the back of the flue where no vine-roots are, places covers on the plants, and in two weeks, when the heat for forcing vines is kept up, he has "as fine sea-kale as could be desired. When a dish is cut, he lifts the roots, and supplies them with the same from the open ground. He considers this a very easy and certain method, especially in a wet climate." (Caled. Hort. Mem. iv. 101.)

3014. Gathering. Remove a part of the leaves, or whatever is employed in blanching; cut off the heads or shoots, and slip off the stalks of the leaves.

3015. Produce. From four to six heads, according to the size, tied together like asparagus, make a dish; and, Maker says, a blanching-pot which contains three plants, will afford a dish twice in a season. Hence, from sixty to a hundred pots will suffice for forcing sea-kale for a large family. From the above data, it is easy to form an estimate of the breadth of ground requisite for plantations of this plant to come in naturally.

3016. To save seed. Let a stool which has not been cut, run in spring; and seed will be produced on every stem.

3017. The artichoke is a perennial, with numerous large pinnatifid leaves, three or four feet long, covered with an ash-colored down; the mid-rib deeply channelled and furrowed. The time of flowering is August and September. It is a native of the south of Europe, and was introduced in England in 1548.

3018. Use. The flower-heads in an immature state contain the part used, which is the fleshy receptacle, commonly called the bottom, freed from the bristles and seed down, vulgarly called the choke, and the tulus or lower part of the leaves of the calyx. In France, the bottoms are very commonly fried in paste, and they form a desirable ingredient in ragouts. They are occasionally used for pickling; and sometimes they are slowly dried and kept in bags for winter use. In France the bottoms of young artichokes are frequently used in the raw state as a salad; thin slices are cut from the bottom with a scale or calyx leaf attached, by which the slice is lifted, and dipped in oil and vinegar before using. The chord of artichokes, or the tender central leaf-stalk blanched, is by some thought preferable to that of the cardoon. The flowers possess the quality of congregating milk, and have sometimes been used in the place of rennet.

3019. Varieties. There are three varieties cultivated: —

Conical, French, or oval Artichoke, with green head. The head is ovate, the scales of pinnatifid form, turned in at the top as in the globe sort.

Globe, or largest, with dusky purplish head. The scales are turned in at the top, and the receptacle more succulent than the other.

The dwarfish globe; a prolific variety, and valuable as occupying little room with its head.

3020. Estimate of sorts. The globe sort is generally preferred for the main crop; but the conical, or French, is generally considered as possessing more flavor, as the flower-heads are cut off for use when in an immature state; both sorts continue producing them from July to November.
3921. Propagation. This esculent is propagated by rooted suckers or young shoots, "rising in the spring from the roots of the old plants; these are fit to slip off for planting in March and April, when from five to ten inches high. Opening the ground to the old stool, slip them off clean to the root, leaving the three strongest on each mother-plant to advance for summer production. Those slipped off, prepare for planting, by pulling away some of the under and decayed or broken leaves, and by pruning any strangling tops of the leaves remaining: also cut off casually hard or ragged parts at the bottom of the root. Then, having an open compartment, with a light rich soil of good depth, well dunged and dug, plant the sets by dibble, in rows four feet asunder, and two feet apart in each row. Give each plant some water: repeat this once or twice, if very dry weather, till they have taken root."

3922. Subsequent culture. "All spring and summer keep them clear from weeds by occasional hoeing behind them, and with regular weather of the dry weather of summer, is all the cultural treatment they require, till the season of production is terminated. They will produce some tolerable heads the same year, in August, and thence till November: next year they will head sooner, in full perfection. By having fresh stools plants every year or two, the old and new plantations together furnish a production of heads from June or July till November. Besides the main head, several smaller lateral heads generally spring from the sides of the stem in succession; but, in order to encourage the principal head to attain the full size, most of the side suckers should be detached in young growth, when their heads are the size of a large egg, which in that state are also prepared for some tables. As to the continuing main heads, permit them to have full growth till the scales begin to diverge considerably, but gather them before the flowers appear, cutting to each head part of the stalk. When the entire crop on a stem is cut, take off the stem close to the ground, to give the plant more strength for new shoots. (Abercrombie.) The main head and the branch heads are generally cultivated in a young state. These are commonly in a fit state for eating raw, having attained about one third of their proper size; and they are for this purpose frequently sold in Covent Garden market, chiefly to foreigners. Another thing practised with the same view is the shortening the ends of the large leaves." (Neill, in Ed. Encyc.)

3923. Nicot mentions, that the strongest crops he ever saw, grew in rather a mossy earth that had been trenched fully a yard in depth, and had been well enriched with dung, and lined; and that the plants were generally raised in a double-littered manner with the manure. This statement, at least, we believe, is one of the very best manures for artichokes. In no place is the plant to be seen in greater perfection than in gardens in the Orkney Islands; and we know that the luxuriance of the plants in these is ascribed to the liberal supply of sea-weed dug into the ground every autumn. It was long ago remarked by a horticulturist, that "water drawn from ashes, or improved by any fixed salt, is very good for artichokes." (Systema Agricultura, 1682.)

3924. Winter dressing. Abercrombie says, "First cut down all the large leaves, but without hurting the small central ones. It is better before the heads begin to detach. Then dig the ground between and around each row forcing it gradually from both sides, ridgeways over the roots, and close about the plants. In rigorous frosty weather, cover also in the litter, a foot thick, and close about each plant."

3925. Spring dressing. In spring, the litter and earth being removed in March or April, according to the kind of season, the stocks are examined; and two or three of the strongest or best shoots being selected for growing, the rest are removed by pressure with the thumb, or by a knife, or wooden chisel. Those shoots or suckers are used for new plantations. Dig the whole ground level, loosen the close up to the crown of the root of every plant.

3926. Duration of the plants. "Artichoke-plants continue productive for several years; but, every season, some well rotted dung or fresh sea-weed, should be delved into the ground at the winter dressing. It is certain, however, that after a few years, the plants begin to degenerate, the heads becoming smaller and less succulent. It is therefore, general rule not to keep an artichoke-plantation beyond four or at most six years. Scarcely any kind of grub or wire-worm ever touches the roots of artichokes: they form, therefore, an excellent preparative for a crop of onions, shallot, or garlic. In many gardens, a small new plantation is formed every year; and in this way the artichoke season, which begins in June, is prolonged till November; a trick which, when the new shoots come in, if the last gathered be cut with the stems at full length, and if these be stuck among moist sand, the heads may be preserved a month longer."

3927. Culture for producing the chard. "When the artichoke compartment is to be shifted, and the old stocks are at any rate to be destroyed, the plants may be prepared, after midsummer, when the best crop of heads is over, for yielding chards against winter. The leaves are to be cut over within half a foot of the stem; the stems as low as possible. In September or October, when the new shoots or leaves are about two feet high, they are bound close with a wreath of hay or straw, and earth or litter is drawn round the stems of the plants. The blanching is perfected in a month or six weeks. If the chards are wished late in winter, the whole plants may be dug up before frost sets in, and laid in sand in their blanched state; in this way they may be kept for several weeks."

3928. Seed. The heads when supposed to remain ten days or a fortnight, after the season of cutting, expand the calyx leaves, and display an aggregation of jagged purple florets, producing a fine appearance. When ripe seed is wanted, those heads in flower are to be bent down and retained in that position, so that as the calyx may throw off the autumnal rains. In general, however, the seed is not perfected in our climate.

3929. The cardoon is a hardy perennial plant, a native of Candia, introduced to England in 1638, and known in all the European languages under the same name. It greatly resembles the artichoke, but rises to a greater height; and becomes a truly gigantic herbageous vegetable of four or five feet in height. It produces flowers like those of the artichoke in August and September. "In France," Neill observes, the native prickly plant is sometimes cultivated under the name of Cardoon of Tours, and is accounted preferable to the common garden variety. So formidable are its spines, that great care is
necessary in working about it, to avoid personal injury; a strong leather dress, and thick gloves, are therefore worn. This prickly sort has not yet been introduced into Britain."

3930. Use. The tender stalks of the inner leaves of the cardoon, rendered white and tender by earthing up, are used for stewing, and for soups and salads, in autumn and winter. When the plants are large, the inner leaves and stalks are rendered by blanching white, crisp, and tender, to the extent of two or three feet. The plant is not in much request, and is only cultivated in some particular family-gardens, and a few market-groinds. On the continent, it is in considerable repute, as indeed are many of salad and pot-herbs, which are comparatively neglected in this country.

3931. Propagation. Though a perennial, it often dies in the winter, and therefore requires to be raised from seed each year, and forced four feet with eight feet; two ounces are sufficient. Formerly the plants were raised on hot-beds, and transplanted in May and June, but now the seed is generally sown where the plants are to remain.

3932. Soil. The best soil for the cardoon is one that is light, deep, and not over rich.

3933. Times of sowing. The chief sowings are made in the spring; for a small early crop, in the last fortnight of March; and for the main crop, in the first or second week of April. Further, for a late full crop, you may sow towards the close of June.

3934. Sowing for transplanting. Sow in a bed of common light earth, moderately thin; and rake in the seed evenly. When the plants have risen, thin them to three or four inches' distance, to give them room to acquire stocky growth for transplanting. When they have been raised about eight weeks, transplant them; allotting an open compartment of well digged ground, and taking an opportunity of rain falling. Having lifted the plants, trim any long straggling tops of the leaves and fibres of the roots. Plant them either in the level ground, or in drills, or form a hollow patch for each plant; in all cases at four feet and a half distance. Thus you will have ample scope for their growth, and considerable space of ground to land them up. Plants are planted, and occasionally till the root take root. In their advancing growth, hoe and loosen the ground about the plants, cutting down all weeds, to the greatest extent.

3935. Sowing to remain. A crop may be raised by sowing where the crops are to remain, not to have any check by removal. Sow in small hollow patches, at the distance specified above, two or three seeds in each. This is stronger to grow, and the plants will remain.

3936. Landing up. When the plants are advanced in large growth, two or three feet high or more, in August, September, and October, proceed to land them up for blanching. First tie the leaves of each plant together with hay or straw bands; then digging and breaking the ground, earth up round each plant a foot or more high or two thirds of the stem. As the stems rise higher, tie and earth them up accordingly, giving them a final earthing in October.

3937. Watering in autumn. Regular waterings in the dry weather of August and September will prevent the plants from seeding.

3938. Taking the crop. When they are blanched a foot and a half, or two feet in length, or more, they may be dug up, as wanted, in September, October, and throughout winter.

3939. Occasional shelter. Protect the plants in severe frost with long litter, either as they stand, or turned down on one side.

3940. To save seed. Leave some full-grown plants in the spring, to shoot up in stalk. (Abercrombie.)

3941. The *rampion* is a biennial plant, a native of England, but rare. The root is long, white, and spindle-shaped; the lower leaves oval-lanceolate, and waved; the flower-stalk is about two feet high, and furnished with a panicle of blue flowers in July and August. The whole plant abounds with a milky juice.

3942. Use. The root is eaten raw like a radish, and has a pleasant nutty flavor; it is also sometimes cut into winter salads, and then the leaves as well as the root are used.

3943. Culture. The seed should be sown in the latter end of May, on a sandy border of rich earth, not over stiff, the mould being made as firm as possible: it is better not to rake in the seed, which, being so very fine, may, by that operation, be buried too deep. If the sowing is earlier than May, the plants will sometimes run to flower in the autumn, and so become useless. Moderate waterings must be given as they come up, through a fine rose, to keep the rose of a pot, and it quite free of weeds, at all times, tolerably moist. When the plants are of sufficient size, they must be thinned out, to the distance of three or four inches apart; those drawn will bear transplanting well, if put into a border similar to the seed-bed, but care must be taken to insert the roots straight into the earth, and not to press the mould too close; the roots which become forked are not so good as the straight ones. In November, the plants will be fit for use, and will continue so until April. (*Dickson, in Hort. Trans.*)

3944. To save seed. Leave or transplant some of the best plants in spring, and they will produce flowers and abundance of seed in autumn.

3945. The *hop* is a perennial plant, a native of Britain, and well known as being cultivated for its flowers, which are used in preserving beer. It rises with a rough shoot, and rough triplicate leaves, the former climbing round whatever comes in its way to a considerable height, and producing flowers of a peculiar odor in July.

3946. Use in cookery. The young shoots, when they have risen three or four inches from the root, were formerly gathered and boiled like asparagus, to which they are very little inferior; these shoots are still occasionally to be found in the market, under the name of hop-tops. A pillow filled with hop-flowers will induce sleep, unattended with the bad effects of soporifics which require to be taken internally.

3947. Culture. The hop is propagated by dividing the roots in autumn or spring. It requires a deep rich soil, which should be frequently turned and kept rich, and the plantation should be renewed every seven or ten years according to circumstances. In field-culture, it is planted in hills or in groups of three or four plants, at six or eight feet centre from centre; but in growing a few for hop-tops, they may be planted in single rows at three feet distance, and one foot asunder in the row.
3948. The alisander is a biennial plant, rising about two feet high, and flowering in May and June; the leaves are of a pale-green color, and the flowers yellowish. It grows naturally near the sea in several places, and may often be observed naturalised near old buildings.

3949. Use. It was formerly much cultivated, its leaf-stalks having been used when blanched, as a pot-herb and salad. It somewhat resembles the celery in flavor, by which vegetable it has been almost entirely supplanted. Some consider the leaves and stalks of the S. perfoliatum, a native of Italy, as preferable to those of this plant.

3950. Culture. “Where the plants are in demand, sow a proportionate crop at the close of March, in the course of April, or beginning of May: either broad-cast, raking in the seed; the plants, when between three and six inches high, to be transplanted into drills, eighteen inches or two feet asunder, by five or six inches apart in each row; or sow at once in drills that distance, to remain, thinning out the superfluous plants in proper time. The seed is sold by weight, and if sown to transplant, for a bed three feet and a half wide by six feet in length (21 superficial feet), half an ounce will suffice; if sown to remain, then for a bed four feet by twenty-four, containing two drills, two feet apart, or for forty-eight feet in length of drilling, then one ounce will be requisite. When the plants are well advanced in growth, earth them up several inches on each side the rows, to blanch the lower parts white, for use in summer, autumn, &c. You may likewise sow a moderate portion in August, to stand over the winter for a supply in spring and the early part of the summer, till the spring-sown plants come in.”

3951. To save seed. The alisander produces nothing fit for the table after the second year; and as it ripens plenty of seed in autumn, it is proper to save some every year for sowing as above. (Alcibermis.)

3952. The bladder-campion is a perennial, growing naturally by the sides of corn-fields and pastures; and also on the sea-shore. The stems are smooth and erect, rising from a foot to eighteen inches high. The leaves are smooth, glaucous, and the flowers in nodding panicles.

3953. Use. Our kitchen-gardens, Bryant observes, scarcely afford a better-flavored vegetable than the young shoots of this plant when boiled. They ought to be gathered when not above two inches long. The sprouts are to be nipped off when of a proper size, and the plants will produce a succession of fresh ones for at least two months.

3954. Culture. A similar culture to that given to the asparagus, or sea-kale, would answer, and probably highly improve this plant. Bryant says, its culture would well reward the gardener’s trouble. Seeds may either be procured from wild plants, or the roots, which run very deep, may be transplanted into deep light soil.

SUBSECT. 9. Thistle. — Carduus and Onopordium, L.; and Cynarocephala, J.

3955. There are two sorts of thistle, which are, or were formerly, used as asparagus-like plants, viz. the milk-thistle, and cotton-thistle.

3956. The milk-thistle, or our lady’s thistle, is the Carduus Marianus, L. (Eng. Bot. t. 976.) It is a biennial plant, a native of Britain, and found in church-yards and near ruined buildings. The plant rises from four to six feet high, furnished with large leaves, covered with an irregular network of beautiful milky veins.

3957. Use. When very young, the leaves are used as a spring salad; and blanched, are used in winter salads; stripped of their spines, they are sometimes boiled and used as greens; and the young stalks peeled, and soaked in water to extract a part of their bitterness, are said to be excellent. Early in the spring of the second year, the root is prepared like salsify or skirret; the receptacle of the flower is pulpy, and eats like that of the artichoke.

3958. Culture. The seeds are sown in a good dry soil, early in February; and when the plants come up, they are thinned out to one foot and a half distance from one another. The intervals are to be kept free of weeds, and stirred occasionally during the summer; and in autumn the leaves are to be tied up like those of endive, and the earth drawn round to blanch them. The blanched herb being cut off far use during winter, the roots remain to be used in spring. 3959. To save seed. Leave one or two plants untied up the first season, and in the second they will produce flowers in July, and seed in August.

3960. The cotton-thistle is the Onopordium acanthium, L. (Eng. Bot. t. 977.) It is a biennial plant, indigenous in various parts of Britain, and remarkable for its large downy leaves and lofty stem, often rising ten feet high, and covering a circle of six or eight feet diameter.

3961. Use. It was formerly used like the artichoke and cardoon; the receptacle and the tender blanched stalks, peeled and boiled, being the parts used.

3962. Culture. The same as the Cardoon. See Subsect. 4.
PLTICE OF GARDENING. Part III.

Sect. VII. Aetarious Plants.

3963. The aetarious vegetables are a numerous class, of various culture, habits, and use, and of which but little that is general can be here observed, excepting that they are all articles of comparative luxury, or condiments, rather than food; and consequently, that though they occupy a moderate portion, perhaps a fortieth of the kitchen-garden, yet, excepting a few of the sorts, as the lettuce, radish, cress, &c. they are seldom found in those of the cottager.

3964. The lettuce is a hardy annual, introduced or cultivated in 1562, but from what country is unknown. Some authors consider it as merely a variety of one of the three native species; one of which, the L. virosa, seems very likely to be the parent plant. The leaves are large, pure white, frequently wrinkled, usually pale-green, but varying much in form and color in the different varieties. Though of but a few months' duration in the same individual, yet, in gardens, by successive sowings in spring, summer, and autumn, it is obtained most part of the year.

3965. Use. The use of lettuce as a cooking and agreeable salad is well known; it is also a useful ingredient in soups. It contains, like the other species of this genus, a quantity of opium juice, of a milky nature, from which, of late years, a medicine has been prepared by Dr. Duncan, senior, of Edinburgh, under the title of Lactuca trium, and which he finds can be administered with effect in cases where opium is inadmissable. (Caled. Hort. Mem. vol. ii. 259.; vol. ii. 314.; and vol. iv. 153.)

3966. Varieties. These are very numerous; and, from the names, many of them appear to have come to us from the Greek islands and the coast of the Levant. The best are —

3967. Estimate of sorts. In their general growth, all the Cos lettuces are more or less upright, of an oblong shape. The cabbage-leTTuces are round-leaved, growing in a compact form, which is not stained, and almost to close the ground. Both have white, close, firm heads when in perfection; the varieties reach maturity from June to August. In the latter half of the year, when the first varieties are very young, the cabbage-leTTuces have a milder, more agreeable taste than the Cos: but when both classes are grown, the flavor of the Cos is preferred for salads, while the cabbage kinds are more used for soups. The cilicias are generally the common kind, and the greatest attention, for they are the first variety to come to perfection, and are the hardest green, the brown Dutch, the common white, and the tennis-ball are the most useful for their hardness in standing severe weather.

3968. Propagation. From seed: of which, for a bed of four feet wide by ten feet in length, a quart of an ounce is sufficient, and will produce upwards of four hundred plants.

3969. Soil and situation. All the sorts grow freely on any rich mellow soil, where the sub-soil is dry. For the most part, raise this vegetable as a principal crop on beds set apart for it; and keep the varieties separate, but to multiply the supplies throughout summer, portions may be sown, thinned intermixed with principal crops of leeks, onions, carrot, and spinach, which will come off before the lettuces are full grown; also, with any young perennials which stand at wide intervals.

3970. Times of sowing. To obtain a constant supply of good lettuces, it is advisable to sow every month, from February to July, for the main summer and autumn crops; and to sow distinct sorts in August and September, to produce late autumn and winter plants, of which a reserve is to stand for spring and early summer heading lettuces in the following year. In the crops, you may begin to sow at the third week of November or the first week of December, but not after, as they should be planted out in the first week of March, on a sheltered south border. Some choice kinds may be sown in February, or in the first week of March, on a sheltered south border. Some choice kinds may be sown in a frame, and forwarded by forcing. But for the main summer crops, sow in March and April, in any open situation. Follow with secondary sowings twice or oftener every month, from May till about the seventh of August; to provide for a succession through the summer, till October, as the plants sown early in the year, after heading fully, soon fly up to seed-stalks. The sowing in the midst of summer should be on shaded borders. For a crop to come in during winter, and stand over partially till spring, make two late sowings, in the third week of August and last fortnight of September.

3971. Process in sowing. The ground should have been broken in the previous digging. sow broadcast, moderately thin; rake in lightly, and very even.

3972. Amount of the summer crops. In the successive crops raised from the opening of spring till the close of summer, when the plants reach about two, three, or four inches' growth, they should be thinned; of those removed let a requisite number be planted out, from a foot to fifteen inches asunder, to remain for cabbaging. Such as continue in the seed-beds may be either gathered thinningly, in progress, or may be sown in the final reserve, if not too close together, and be planted out at the square distance specified above, especially those designed to stand till of stocky growth. In dry weather, water well at transplanting. Also weed and hoe the beds thinned, and water them, if necessary. In the first heading crop of Cos lettuces, when about three parts grown, and beginning to close the inner leaves, a number may be forwarded in cabbaging, by tying the leaves together, moderately close, with strings of bass; the remainder will head and whiton, in due time, without this assistance. Under the
above culture, the successive crops will advance freely to a stocky growth: the earliest will cabbage moderately in May, but more fully in June, and in perfection in July and August.

3973. Crop raised on heat. "For an accelerated crop, some may be sown in the beginning or middle of February on a gentle hot-bed. When the plants are one or two inches high, in March or April, prick a portion either into a warm border, if a mild season, and let them be shielded with mats, during nights and bad weather; or into a frame or slender hot-bed, to bring them more forward. According to their progress, in April or May, transplant them into the open garden, from six to twelve inches asunder, to remain for heading."

3974. Winter-standing crop. "To have lettuces for drawing in minor growth for use, during winter, and to stand over in part for returns in a maturity stage, early next spring and the beginning of summer, sow in the third week of August and in the first fortnight of September, the suitable hardy sorts. You may, for this purpose, sow one or two smaller plants into a winter border, or to a winter warmer; if deficient in frames and glasses, you may transplant a part into a south border, to be arched over with hoops, and covered occasionally with mats; or, as the young plants are tender in winter, protection, afforded in some of these ways, will preserve them more effectually in rigorous weather. During the winter, let the lettuces be thinned by hand-lights, have watered with a winter warmer; but let them be defended always at night with the glasses, and with mats or other additional covering in intense frost or very rigorous weather: in the day-time, protect them from heavy rain, snow, and frost, but so as to let the light in; also, in a severe season, a covering with glasses, and earth borders with mats, light straw-litter, or fern, or occasionally with reed panels, or wattled hurdles, placed alternately over the wall. These coverings should be continued only in rigorous frosts, and removed when the weather is open. Then in the spring, about March or April, the plants in open borders, which have survived the winter, will be thinned, so as to stand from six to twelve inches apart; and those thinned out may be planted in another compartment at the same distance. At the same period, all the lettuces which have wintered under frames, hand-glasses, or mats, should be transplanted into the open garden. In their final stations, the whole will advance to useful sizes in the course of April, or will reach full growth with stocky heads in May. At this season, they may be supplied with the usual attention in a winter warmer; and in April or May, the plants first sown in the current year can have good heads in June and July. Winter and early spring lettuce may be further accelerated by transplanting some of the strongest autumn-raised plants, intermediately protected, as above, by frames or glasses, into hot-beds, or the borders of forcing-stoves: transplant the lettuces to be thus forced, with a plastic of earth about the roots, in December, January, and February. Those excited by heat in December, will have cabbaged hearts by the beginning of March.

3975. To save seed. "Leave or transplant either some of the early winter-standing plants, in March or April, or of the forwardly spring-sown crops, in May or beginning of June, fifteen inches asunder. They will produce ripe seed in August and September." (Abercrombic.)

3976. The endive is a hardy annual, of native of China and Japan, and introduced in 1548. The root-leaves are numerous, large, sinuate, toothed, and smooth; the stem rises about two feet high, is branched, and produces pale-blue flowers in July and August.

3977. Use. "It is cultivated for the stocky head of leaves, which, after being blanched to take away the bitter taste, are used in salads and stews in autumn, winter, and spring. It is in great repute both in England and on the continent.

3978. The varieties are —

Green curled-leaved; principal sort for the main crops | Broad-leaved Batavia; of largest upright growth.

White curled-leaved

3979. Estimate of sorts. "All the sorts are eligible for culture; but allot, principally, the green curled for the main crops of autumn and winter endive, this being the most stocky full growth, and hardest to stand severe weather. As to the others, allot a smaller portion of the white curled for early summer and autumn use: of the broad-leaved kind, provide a moderate crop for a summer endive, till November or December: being by some esteemed preferable for stews and soups, though not much used in salads."

3980. Propagation. All the varieties are raised from seed, of which, for a seed-bed four feet wide by ten in length, half an ounce is sufficient.

3981. Times of sowing. The proper seasons are, May for a smaller early crop; and principally June and July to the beginning of August; for full and succession crops, all autumn and winter, till the following summer. Lettuces raised in March or April, towards the end of June, may begin sowing moderately of the different sorts; but do not sow fully till nearly the middle of July, that the plants may stand without running the same year. About the twelfth and twentieth of that month, also at the beginning and middle of July, sow the main
and succession crops for autumn and winter; and a finer smaller sowing about the beginning of August, for late supplies in the end of winter and following spring.

3982. Culture in the seed-bed. Sow each sort separately in beds of rich mellow earth, in an open situation; scattering the seeds thinly, and rake in the seed. When the plants are up an inch or two in growth, thin them moderately, where in clusters, that they may have room to grow stronger and stocky for transplanting. But if a portion are sown in soil of sufficient depth, and thinned to the distances mentioned under transplanting, instead of being moved, they may be expected to yield heads of the finest kind, under the same culture as is given to the others.

3983. Transplanting. As the plants attain a sufficient growth, being from four to six inches high, or in a month or five weeks from the time of sowing, proceed to transplant the successive crops. The ground should be light and rich on a dry sub-soil. Dig it a full spit deep; set in shallow trenches, or drills the depth of a hoe, endive blanches with less trouble than if inserted on a level surface. The lines may be fifteen inches asunder; the plants ten or twelve inches distant in the line. Drawing the strongest first, plant out portions from June till October; but the principal removals will fall in August; in which months three different plantings may be made for succession; also for a general winter crop, at the beginning of September. While the plants are in hand, trim the extremities of the leaves, and shorten the top roots a little. Water at planting; and moderately afterwards once in two days, if the weather be dry, till the plants take root. At the end of September, and in October, likewise plant some in a warm dry border, to stand the winter more effectually. Also, in the last fortnight of October or beginning of November, it would be proper to insert some stout plants thickly on a bank of dry light soil, raised a foot or two behind, sloping to the south. Thus they will remain drier in winter, and will be preserved more securely from rosetting in that season. The bed might be also defended in severe weather with frames and glasses, or with an occasional awning of mats or sail-cloth.

3984. Grange. Of Kingsland, transplants in October, on sloping banks, at the base of hedges or walls; or if these are not to be had, he forms banks with a slope of 45 degrees facing the south. The north of the face of the bank measures five feet; along it he places four rows of plantlets stuck more than half way into the earth with the convex side to the sun. A plant of entide is then placed opposite the concave side of each tile, the latter serving to keep its leaves dry. In winter these banks are covered with dippings of hays or straw to keep them dry, as they exclude the frost.

3985. Blanching. As the transplanted crops advance to full growth, stocky and full in the heart, some should have the leaves tied up every week or fortnight, to Blanch or whiten, and to render them tender, crisp, and mild-tasted. Perform this in dry days; and in winter, when the weather is dry without frost. Using strings of fresh bass, or small wister twigs, tie the leaves regularly together a little above the middle, moderately close. If the soil be light and dry, earth them up half way; but if moist, merely tie them. The two curled sorts, if neatly earthed up, will branch pretty well without being tied. The Batavian, from its length, in every case and branches better with a blade. The blanching is generally completed sometimes in a week, when the weather is hot and dry; at others, it may take a fortnight or three weeks; after which the entide should be taken up for use, or it will soon rot, in six days or less, especially if much rain fall. To save the trouble of tying, this esculent is also occasionally blanched by setting up flat tiles or boards on each side of the plants, which, resting against other in an angular form, and confined with earth, exclude the light. Further, entide may be blanched under garden-pots, or blanching-pots, in the manner of sea-kale. In the heat of summer and autumn, tying up is best; but in wet or cold weather, to cover the plants preserves while it blanches them.

3986. Seed. At the first formation of seed, some portion of the flowers are up the thickly with straw-litter. Also plunge a portion into a raised bank of light dry earth, under a glass-case, or covered shed, open to the south. Protect with litter in rigorous weather; but uncover, and give plenty of air on mild days.

3987. Allot some of the strongest old plants in February or March, if any remain; otherwise, sow seed in March or April, and transplant or thin the plants to twelve or fifteen inches' distance. They will shoot, and the seed ripen in autumn.

3988. The succory, or chicory, is a hardy perennial not uncommon in calcareous wastes and by road sides. The whole plant greatly resembles the common broad-leaved entide; the leaves are runcinates; the stem rises from two to four and five feet high, producing blue flowers from June to August. The plant is but little cultivated in gardens in this country, though it is in much repute on the continent, and especially in Italy. It has been grown in the fields, in France and England, as a fodder for cattle, when coming into flower; and is at present much cultivated in Holland and Flanders, for the roots, which are dried, and ground, and used on almost every part of the continent, partly along with, and partly as a substitute for coffee, by those who cannot afford to use that article genuine; but Miller and other English authors on horticulture do not notice it as an article for the garden.

3989. Use. The leaves are blanched and used as those of entide, or during winter forced in the dark, and so blanched. In this state it is the Barbe de Capucin of the French. It is also sown thick in frames, and in the open air, and when it has produced two rough leaves, cut as a small salad. When lettuce or garden-endive is scarce, chicory can always be commanded as salading by those who possess any of the most ordinary means of forcing. The roots cut in pieces, dried and ground, afford a powder, which Dr. Howison (Caled. Hort. Mem. iv. 132.) thinks preferable to that of coffee; and Dr. Duncan (Disc. to Caled. H. S. 1820) is of opinion that the plant might be cultivated with great national advantages, as a substitute for that exotic berry. About Bruges, the
roots are scraped and boiled, and eaten along with potatoes, or with a sauce of butter and vinegar.

3990. Varieties. The French have the common large-leaved, the chicorée à nœud, or café-chicorée, with large white fleshy roots, and the variegated chicory.

3991. Culture. Isaac Oldacre, an excellent practical gardener, who experienced the advantages of cultivating this plant in the Imperial gardens near Petersburg, gives the following directions. "It should be sown in the end of June or beginning of July, on a rich piece of ground, broadcast, in the same manner as endive; when the leaves begin to cover the ground, thin out the plants, leaving those that remain on the beds from three to four inches apart; those pulled out may be planted into other beds, at the same distance as those which are left to remain; keep them clear from weeds, and if the leaves grow very strong, and shade the roots much, cut them off within one inch of the ground. The end of September or beginning of October is the proper time to shift the roots; the leaves should be first cut off with care, so as not to destroy the hearts of the plants, then dig up the roots, shorten them, and plant them in pots or portable boxes, with a dibble, very close together and rather deep. Give them water when dry, and shelter them in severe frosts, by a light covering of litter. After they are well rooted, the pots or boxes, as wanted, are to be removed into the mushroom-house or cellar, where they must be entirely excluded from light, in order to blanch the leaves, which will be effected in six or seven days. Success will thrive in a heat of sixty degrees, but it is best to keep it in a lower temperature. If the roots are strong, each pot or box will bear cutting twice, after which they should be removed, and changed for the succession, as the leaves of the future growth become bitter. (Hort. Trans. vol. iii. p. 139.)"

3992. Crop in cellars. On the continent, the roots are taken up on the approach of winter, and stacked in cellars in alternate layers of sand, so as to form ridges with the crowns of the plants on the surface of the ridge. Here, if the frost be excluded, they soon send out leaves in such abundance as to afford a supply of salad during winter. If light is excluded, the leaves are perfectly blanched, and in this state are known under the name of Barbe de Capucin. On ship-board it is customary to use a barrel of sand with numerous holes (fig. 470), or a hamper, for the same purpose.

3993. To save as directed for endive.

3994. The dandelion is a hardy perennial, a native of Britain, well known among gardeners as a troublesome weed, but which may also be used as a salad, and as a substitute for coffee.

3995. Use. The leaves in early spring, when just unfolding, afford a very good ingredient in salads. The French sometimes eat the young roots, and the etiolated leaves, with thin slices of bread and butter. When blanched, the leaves considerably resemble those of endive in taste. The root is considered an equally good substitute for coffee as chicory, and may, like that plant, be stored in cellars or barrels for producing winter salad. (Caled. Hort. Mem. iv. 138.)

3996. Culture. Though regularly produced in the London market, it is seldom or never cultivated, being generally to be found in sufficient luxuriance by the sides of hedges and dry ditches. It might easily be propagated either by seeds or roots; and, if introduced as a garden-plant, should have a rich deep soil, and be carefully tied up, and earthed round, to blanch it effectually. Cut off all the flowers as they appear, to prevent the dispersion of the seed, and the weakening of the plant. When salad is scarce, the dandelion might be dug up from road sides in winter, and forced in pots, like succory.

3997. The celery is a hardy biennial plant, a native of Britain, and known in its wild state by the name of smallage. It is frequent by the sides of ditches, and near the sea, where it rises with wedge-shaped leaves, and a furrowed stalk producing greenish flowers in August. The whole plant has a rank coarse taste, and the effects of cultivation in producing from it the mild sweet stalks of celery are not a little remarkable. A head of celery, we are informed (Caled. Hort. Mem. vol. ii. p. 297.), was dug up on the 4th of October, 1815, at Longford, near Manchester, which weighed 9 lbs. when washed, with the roots and leaves still attached to it, and measured four feet six inches in height. It was of a red sort, perfectly solid, crisp, and firm, and remarkably well flavored.

3998. Use. The blanched leaf-stalks are used raw, as a salad, from August till March; they are also stewed, and put in soups. In Italy, the unblanched leaves are used for soups, and when neither the blanched nor the green leaves can be had, the seeds bruised, form a good substitute. The root only of the variety called the celeriac is used, and Sabine informs us (Hort. Trans. vol. iii.) "it is excellent in soups, in which, whether white or brown, slices of it are used as ingredients, and readily impart their flavor. With the Germans, it is also a common salad, for which the roots are prepared by boiling, until a fork will pass easily through them; after they are boiled, and become cold, they are eaten with oil and vinegar. They are also sometimes served up at table, stewed with rich sauces. In all cases, before they are boiled, the coat and the fibres..."
of the roots, which are very strong, are cut away; and the root is put in cold water, or the fire, not in water previously boiling."

3999. Varieties. These are—

The common upright Italian
The large-leaved upright
The solid-stalked upright
The turnip-rooted, or clericia, the cler-icaria, of the French, and the koeltz-clericia, of the Germans. This is harder than the other kinds, and will continue longer in spring. It is grown to a large size in the neighborhood of Hamburg, and sometimes imported for the London market.

4000. Estimate of sorts. The first three sorts are preferable for general culture. The red variety is rather coarse for salads, but it is hardy to stand the winter, and well adapted for soups and stews. The turnip-rooted is cultivated on account of its root, which is fit for use in September and October, and may be preserved in sand through the winter.

4001. Propagation. All the sorts are raised from seed; and half an ounce is reckoned sufficient for a seed-bed four feet and a half wide by ten feet in length, of the upright sorts; but for clericia, a quarter of an ounce will be enough for a bed four feet square.

4002. Soil. Celery delights in a soil rather moist, rich in vegetable mould, but not rank from new unrotted dung.

4003. Times of sowing. The most forward crop is slightly forced: any of the varieties may be sown in the spring, in the open garden, at two or three different times, from the 21st of March till the first week in May; but the principal sowing should be made in the first fortnight of April.

4004. Early crop. "For early summer and autumn celery: sow a small portion towards the end of February, in a moderate hot-bed. When the young plants are about two inches high, prick out some into a warm border, two or three inches apart, or rather into a second slight hot-bed, if before the 21st of March the large-leaved sorts are well to protect the plants as to expedite their growth for final planting. As soon as the leaves are six inches high, in May or June, transplant them into trenches for blanching, as directed below for the main crops, but as these early-sown plants will continue long in full growth, before many of them will be ready for run, you should plant only a moderate crop, for a temporary supply: when they are advanced in the trenches from eight to twelve inches in growth, begin to earth them up several inches on both sides each row; continue earthing up by degrees as they rise higher, till they are whitened from six to twelve inches in length; when they may be digged up as wanted."

4005. Main crops. "To raise the main crops for summer, autumn, and winter, make a considerable sowing at the commencement of April. Sow in beds of light mellow earth, and rake in the seed lightly and regularly. In very dry weather, give moderate watering both before and after the plants come up. When they are two, three, or four inches high, thin the seed-bed, and prick out a quantity at successive times into intermediate beds, three or four inches asunder. Water those removed, and till they have struck.

4006. Judd sows about the middle of January in a warm situation, on very rich ground, protecting it by mat at night. When the plants are from two to three inches high, he pricks out into a nursery-bed, and takes them from thence, as he draws them, in water, so as they may remain moist while out of ground. The plants remain in the nursery-bed till they become "very strong." (Hort. Trans. vol. ii.)

4007. Walker, a gardener, near Manchester, grows the red celery; sows for the early crop about the 1st of March, and for the late crop about the 1st of April. The seed-bed is formed of fresh, dark, loamy soil, mixed with old rotten dung, half and half, and placed on a hot-bed. The nursery or "transplanting bed is formed with old hot-bed dung, very well broken, laid six or seven inches thick, on a piece of ground which has lain some time undisturbed, or has been made hard by compression. The situation is sunny. The plants are set six inches asunder, and three inches deep; the dead leaves are removed, and hand-glasses. They are watered well when planted, and frequently afterwards. By hardening the soil under the dung in which the plants are set, the root is formed into a brush of fibres; and by thus preventing the pushing of a tap-root, the plant never runs to seed before the following spring." (Caled. Hort. Mem. vol. ii.)

4008. Transplanting into trenches. "When either the plants left in the seed-bed, or those removed, are from six to twelve inches high, or when the latter have acquired a stocky growth, by four or five weeks' nurture in the intermediate bed, transplant them into trenches for blanching. For this purpose allot an open compartment. Mark out the trenches a foot wide, and from three feet to three and a half distance; dig out each trench lengthwise, a spade in width, and a light split deep, that is, six or eight inches. Lay the excavated earth smoothly in the intervals, making the edges of the trenches equally full and straight; also loosen the bottom moderately, in a level order, to receive the plants. Before inserting them, it would essentially strengthen the soil to apply some good rotten dung in each trench two or three inches thick, and let it be digged in at the bottom regularly, a moderate depth. Then having lifted the plants, just trim any long straggling tops of the leaves and fibres of the roots; also slip off side shoots; plant a single row along the bottom of each trench, four or five inches apart. Give a good watering directly; and occasionally after, if the weather be dry, till the plants take root and show a renewed growth. Continue planting out a monthly succession in June, July, August, and September; thus providing for a supply from July and August of the present summer throughout the course of autumn and winter, till May in the following spring."

4009. Judd prepares his ground for transplanting, by trenching it two spades deep, mixing with it in the operation a good dressing of well reduced dung from the old forcing-beds. He says, "I give it a second trenching, that the dung may be the better incorporated with the mould, and then leave it in as rough a state as possible, till my plants are ready to be put out. In the ground thus prepared, I form trenches twenty inches wide, and six inches deep, at six feet distance from each other, measuring from the centre
of each trench. Before planting, I reduce the depth of the trenches to three inches, by digging in sufficient depth to fill them up entirely. At the time of planting, if the weather is very dry, the trenches are well watered in the morning, and the plants set in, six inches apart, in the row, in the evening. I am being taken by the mode above mentioned, to keep the fibres quite wet whilst out of ground: as they are drawn from the nursery-bed, the plants are dressed for planting, and then lined regularly in the garden-pan. The common celery is planted, being as very shallow, the roots of the plants grow nearly on a level with the surface of the ground: this I consider particularly advantageous; for as considerable cavities are necessarily formed on each side when the moulding takes place, all injury from stagnant water or excess of moisture is prevented. The trenches, when planted, are watered as may be required. "

4011. Landing up. As the plants in the trenches rise from ten to fifteen inches high, Abergrombie begins to land up for blanching, observing "to trim in the earth gently, when first raised to the stems, with a hoe or spade, but mostly the latter. When the plants are of more advanced growth, earth them up equally on both sides each row, three, four, or five inches, according to the strength and height of the different crops. Repeat this once a week or fortnight, till by degrees they are landed up from twelve inches to two feet, in order to blanch them of some considerable length. Continue thus landing up the different crops from July till February. As the autumnal and main winter crops attain full growth, give them a final landing up near the tops, which will increase the length of the blanched part, and also protect the latter crops more effectually during the winter."

4012. Judd, in landing up celery, does "not think it well to load the plants with too much mould at first; the two first mouldings, therefore, are done very sparingly, and only with the common draw-hoe, forming a ridge on each side of the row, and leaving the plants in a hollow, to receive the full benefit of the rain and waterings. When the plants are strong enough to bear six inches height of mould, the moulding is done with the spade, taking care to leave basis enough to support the mass of mould which will ultimately be thrown over the ridge, and still keeping for some time the plants in a hollow, as before directed. The process of moulding is continued through the autumn, gradually diminishing the breadth of the top, until at last it is drawn to as sharp a ridge as possible to stand the winter. In the operation of moulding it is necessary, in order to prevent the earth from falling into the heart of the plant, to keep the outer leaves as close together as possible; for this purpose, before I begin the moulding, I take long strands of last matted line together till sufficient length to answer for an entire row; and I fasten this string to the first plant in the row, then pass it to the next plant, giving it one twist round the leaves, and so on, till I reach the other end, when it is again fastened; when the moulding is finished, the string is easily unravelled, by beginning to untie it at the end where it was last fastened."

4013. Walker "having removed the lateral shoots, the leaves of each plant being held together with one hand, the soil, pulverized, is drawn round with the other, taking care not to earth up too high at once, nor too close. The heart should always be left quite free. This may be repeated about once a fortnight, until the plants are ready for use."

4114. Late crop. "For late spring celery to stand till the end of May in the returning spring, without running considerably, it is expedient to make a small late sowing at the commencement of May. The plants when six weeks old may be pricked on intermediate beds in rows, six inches by three asunder; to remain till September or October; then transplant them into moderate trenches; as they advance in growth, earth them up a little in winter; and, finally, in the spring, in February or March."

4015. Occasional shelter. "On the approach of frost, take up a part of the crop, and lay it by under dry sand for winter. To preserve the plants left in the bed, lay some long dry litter over the tops; which remove in every interval of mild weather. " It is a common complaint that very fine looking celery is often found to be rotten at the base of the leaf-stalks; the fact being, that when celery is full grown and the blanching completed, it begins to decay, and will not keep good in the ground for more than a month at most. Some, therefore, take up and preserve in dry sand; but in that situation it soon becomes tough and dry. The best mode seems to be that of forming successive plantations."

4016. Taking the crop. "It is best to begin at one end of a row, and dig clean down to the roots, which then loosen with a spade, that they may be drawn up entire without breaking the stalks."

4017. Cultivation of celeriac. The times of sowing are the same as for the other sorts. Celeriac requires a rich well manured soil, and, according to an account communicated by Lord Stanhope to Sabine (Hort. Trans. iii.), the plants are raised on a hot-bed under glass, and transplanted when two or three inches high to another hot-bed, and set one inch and a half apart. "In the beginning or middle of June they are transplanted into a flat bed in the open air, at the distance of fifteen inches from each other, and not in trenches like other celery. They must be abundantly watered as soon as they are set out, and the watering must be repeated every other day, or, if the weather should be warm, every day. As they increase in size, they will require a greater quantity of water, and they must be occasionally hoed. The roots will be fit for use in September or October." In a note to this paper, Sabine states, that he has been informed, that
the plan of giving excess of water is peculiar, and that the vigorous growth of the plant is more dependent on richness of soil than on any other cause. Abercrombie directs to earth up the bulbs four or five inches, to Blanch them when they are full grown.

4018. To save seed. "Either leave some established plants in the spring where growing; or in February or March dig up a competent number, cut down the top leaves, and set the plants in the ground, full two feet asunder. They will produce seed in autumn."

4019. Walter grows only red celery; and in preparing plants for seed, chooses the most solid, of the reddest color, and the smallest size. When taken out of the transplanting-bed, the lateral shoots being removed, they should be planted in a dry warm situation, where the seed will ripen well.

4020. Of mustard there are two species in cultivation, the black and the white; annually, and natives of Britain.

4021. The white mustard is the Sinapis alba, L. (Eng. Bot. t. 1677.) It grows naturally in corn-fields, and flowers in June and July. The leaves are pinna, the pod round and rough, and abruptly terminated. The seed is yellow, and, as well as the flowers, is larger than those of the black species.

4022. Use. This species is cultivated chiefly as a small salad, and is used like cresses in the seed; when these are newly expanded, they are mild and tender; but when the plants have advanced into the rough leaves, they eat rank and disagreeable.

4023. Culture. For spring and summer consumption, sow once a week, or fortnight, in dry warm situations, in February and March; and afterwards in any other compartment. "In summer, sow in shady borders, if it be hot sunny weather; or have the bed shaded. Generally sow in shallow flat drills, from three to six inches apart; scatter the seed thick and regular, and cover in thinly with the earth, about a quarter of an inch. To furnish gatherings in winter, or early in spring, sow in frames or under hand-glasses; and when the weather is frosty or very cold, in hot-beds and stoves, as directed for cress."

4024. To save seed. Either sow a portion in March or April, to stand for that purpose; or, for small supplies, leave some rows of the spring sowing, grown too large for salads; they will ripen seed in autumn.

4025. The black mustard is the S. nigra, L. (Eng. Bot. 969.) the senev of the French. It is frequent in corn-fields. It is altogether a larger plant than the white, with much darker leaves, and their divisions blunter. The flowers are small, the pods smooth, and lying close to the stem.

4026. Use. Black mustard is chiefly cultivated in fields for the mill, and for medicinal purposes. It is sometimes, however, sown in gardens, and the tender leaves used as greens early in spring. The seed, in common with those of the cress, radish, rape, &c. are sometimes used as a salad ingredient; but the grand purpose for which the plant is cultivated is for seeds, which, ground, produce the well known condiment. If the seeds, Dr. Cullen observes, be taken fresh from the plant, and ground, the powder has little pungency, but is very bitter; by steeping in vinegar, however, the essential oil is evolved, and the powder becomes extremely pungent. In moistening mustard-powder for the table, it may be remarked, that it makes the best appearance when rich milk is used; but the mixture in this case does not keep good for more than two days. The seeds of both the black and white mustard are often used in an entire state medicinally.

4027. Culture for the mill. "To raise seed for flour of mustard, and other official occasions sow, either in March or April, generally the black sort, or occasionally the white, in any open compartment; or make large sowings in fields, where designed for public supply. Sow moderately thick, either in drills from six to twelve inches asunder, or broad-cast, and rake or harrow in the seed. When the plants are two or three inches in the growth, hoe, or thin them moderately, where too thick, and clear them from weeds. They will soon run up in stalks; and in July or August return a crop of seed, ripe for gathering."

(Abercrombie.)

4028. The rape is a biennial plant, a native of Britain, and distinguished by its glaucous root-leaves, and yellow flowers, which appear in April.

4029. Use. Rape is cultivated in gardens as a small salad herb, to be gathered young in the seed-leaves, and used in cresses and mustard. Like these, it has a warm flavor, and is recommended as a stomachic. The plant is also much used in agriculture.

4030. Culture for small salading. Sow at the same time with cresses, mustard, &c. in winter and spring; or at any season when small salading is required. Sow in drills or beds, and follow the culture directed for White Mustard.

4031. To save seed. Transplant two or three plants any time during the summer, and they will flower and seed the second year abundantly.

4032. The corn-salad is a diminutive annual plant, common in corn-fields or sandy soils. The leaves are long and narrow, of a pale glaucous hue, the lower ones rather succulent. The flowers are very small, pale-blush, and collected into a close little corym; they appear in the open fields in April. When cultivated, it rises a foot high,
and flowers in March. Gerrard tells us, that foreigners using it while in England, led to its being cultivated in our gardens.

4033. Use. It is used in salads through winter and early spring; both as a substitute for common lettuce in those seasons, and to increase the variety of small salads. For these purposes it has long been a favorite plant in France, under the denomination of mâche, doucelle, salade de chamoine, and poule grasse.

4034. Propagation. It is raised from seed, of which a quarter of an ounce is sufficient for a bed four feet by five.

4035. Times of sowing. To answer the common demand, two or at most three sowings will be sufficient. The first sowing at the beginning of March; the second sowing at the beginning of April; and the third and last sowing at the beginning of May, to furnish together crops in winter and early spring; and a smaller sowing in spring, the close of February or course of March, if the plants are required in continuation throughout that season though they are apt to get rank-tasted in warm dry weather. If wanted throughout summer, sow once a month, and the crops will be quite young.

4036. Culture. "Sow in any bed of common mellow earth, broad-cast, and rake in the seed. When the plants are up, thin them two or three inches asunder, that they may have room to acquire some small stocky growth for gathering."

4037. To sow seed. "Leave some plants in spring; they will produce seed in July or August." (Abercrombie.)

4038. The garden-cress is a hardy annual plant, cultivated since 1548; but its native country is unknown. The cultivated plant rises with numerous long leaves, curled or plain; from which proceeds a stalk from fifteen to twenty inches high, furnished with white flowers, which blossom in June and July. The whole plant partakes strongly of the pungent smell and acrid taste which distinguish the Cruciferae.

4039. Use. It is cultivated in gardens for the young leaves, which are used in salads, and have a peculiarly warm and grateful relish. It ranks among gardeners as the principal of the small salads.

4040. Varieties. These are —

The common plain-leaved; principally | Cultivated | Broad-leaved; less cultivated for salading; commonly grown for bearing turnips, &c.

4041. Propagation. All the varieties are raised from seed, of which one ounce or one eighth of a pint will suffice for a bed four feet by four feet.

4042. Times of sowing and site of the crop. "Cress should be raised three or four times every month, as it may be in demand, to have crops delicately young in constant succession. For culture in the open garden, begin in the first, second, or third week in March, as a forward spring may bring mild weather or otherwise; allot some warm situation for the early spring sowings; and if the weather take a cold turn, either put on a spare frame, or cover with matting between sunset and sunrise. When spring is confirmed, sow in any open compartment. At the beginning of summer, the same; but, in hot dry weather, either sow in a shady border, or if the situation be open, shade with mats in the middle of the day. For autumn sowings, when cold weather is approaching, allot some warm borders, and give occasional protection. When crops are in demand throughout winter, either sow in a moderate hot-bed, or in cradles to be placed in a stove; pans filled with rotten tan are to be preferred to pots or boxes with mould. From the last fortnight of October till the first of March, it will be mostly fruitless to sow in the open garden, but a terrace, sloping south under a frame, may be used at the decline of the year and most early part of spring, as the intermediate step between the open garden and hot-bed, if more within the means at command. During this interval, some market-gardeners sow it just within the glasses which cover the cress; it is raised on porous earthen-ware vessels, of a conical form, having small gutters on the sides, for retaining the seeds. These are called pyramids, are somewhat ornamental in winter, and afford repeated gatherings.

4043. Process in sowing and subsequent culture. "Having allotted a fine mellow soil to receive the seed, dig the surface, and rake it finely preparatory to sowing, which mostly perform in small, flat, shallow drills, four, five, or six inches asunder. Sow the seed very thick, and earth over very lightly, or but just thinly cover. Give occasional waterings in warm dry seasons."

4044. Taking the crop. "To gather cress in perfection, cut them while moderately young, either clean to the root, or only the tops of advanced plants. They will shoot again for future gathering, but the leaves will be hotter, and not so mild and tender as those of younger plants."

4045. To save seed. "Either sow a portion in the spring for that purpose; or leave some rows of any overgrown old crop in April and May. The plants will yield seed in autumn."

4046. The American cress is a native of Britain, and was found in watery places; and was formerly considered as a variety of the common winter cress (E. Barbarea); but, as observed by Neill, it is only biennial; while the common winter cress is perennial. It has smaller leaves, more frequently sinuated; the lower are lyre-shaped, and those on the stalk pinnatinate. It is often called black American cress, and sometimes French cress.

4047. Use. It is generally liked as a winter cress and early spring salad, resembling in flavor the common winter cress, but rather more bitter. It is in demand in some families throughout the year.

4048. Culture. It is raised from seed, which is sold by weight, and for every ten feet of drill, a quarter of an ounce will be requisite. "Sow in a bed of light dry earth, rather in drills nine inches apart, than broad-cast. For winter and spring use, make a sowing in the last fortnight of August, or beginning of September, on a warm sheltered border. If wanted throughout summer, sow every six weeks from March to August, giving a sunny or shady situation according to the advancement of the season. Water occa-
sionally in dry hot weather. At the approach of winter, shelter the plants, by laying a few light twigs among them so as not to interfere with their growth; and upon these, a covering of fern, reeds, or dry litter. The plants being cut, or the outside leaves stripped off, shoot again for another gathering." "4049. To save seed. Let a few choice plants, raised in spring, run; and they will ripen seed before the decline of summer." (Aberricornic)

4050. The winter cress is a well-known perennial plant, common in moist shady situations. The lower leaves are lyre-shaped, and the upper obovate and indented. The flower-stalk rises about a foot high, and produces yellow flowers from April to August. The whole plant is bitter and somewhat aromatic. Nell observes, "Some still consider the American cress of gardeners as a variety of this; but after cultivating both for several years, we have found those to be right who regard them as distinct." A double variety of Barbarea is well known in the flower-border as the yellow rocket of gardeners.

4051. Use and culture. The same as the American cress.

4052. Water-cress is a creeping amphibious perennial, growing in wet ditches and slow running streams. The stems are spreading, declining or floating, if in water. The leaves are alternate, pinnate, and somewhat lyre-shaped. The flowers are white in a corymb, soon lengthened out into a spike in June and July. The plant, when growing in a rapid current, has its leaves lengthened; and in this state, Martyn remarks, is sometimes mistaken for the water-parsnip (Sturm notiflorum, L.), which commonly grows with it, and is deleterious.

4053. The cultivation of the water-cress is said to have been first attempted in 1668, by Bradbury, at Northfleet Spring-Head, near Gravesend. This cultivator now grows five acres at West Hyde, near Rickmansworth: he sends the cress in hampers, each containing eight dozen bunches, to the London markets every day throughout the year, excepting Sundays, and in consequence of this and other supplies from artificial sources, the wholesale price of the article is reduced one half. There are now several cultivators of this cress at Hackney, Basset Wood, Uxbridge, and other places. Water-cresses are also cultivated near Paris. (Neill, in Hort. Tour. 490.)

4054. Use. It forms an excellent spring salad either alone or with brook-lime or scurvy-grass. It is a popular favorite in spring in most places; and is eaten fasting, or with bread and butter, by those who have faith in its antiscorbutic virtues. The juice is decocited with that of scurvy-grass and Seville oranges, and forms the popular remedy called spring juices.

4055. Varieties. Bradbury considers that there are three, the green-leaved, the small brown-leaved, and the large brown-leaved. The green-leaved is the easiest cultivated, the small brown-leaved the hardest, and the large brown-leaved the nicest. It is the best for forage in deep water, and that preferred by this cultivator.

4056. Culture. The most suitable description of water is a clear stream, and not more than an inch and half deep, running over sand or gravel; the least favorable, deep still water on a muddy bottom. It is highly advantageous to make the plantations parallel to the current, even when it is still, but if any obstruction to the stream or flow of water, the plants cease to thrive. After the plants have been cut about three times, they begin to stock, and then the often they are cut the better; in summer it is necessary to keep them very closely cut; and in water of a proper depth, and with a good soil, each bed supplies a gathering once a week. In water of the same depth, the water should be rather deeper than in summer (four or five inches); to obtain this, the plants are left with more head, that the water may thus be impeded.

4057. Replanting. The most expensive part of the cultivation is the necessity of cleaning out and replanting the beds twice a year, and of making them quickly over the roots, and the duck-weed and other plants become intermixed with, and choke up the cress; it is almost impossible to pick it in a fit state for market after the plantation has been made five or six months. The mode of replanting is to remove all the roots of plants, beginning at the stream head, and then clear the bed of the stream from mud and rubbish; if it should be choked with weeds, make an attempt to clean it, thus taken out, the youngest, and those with most roots, are selected; these are placed on the gravel in rows at the requisite distance, with a stone on each plant, to keep it in its place. The times of renewing the beds are in May and June, and from September to November. The plantation is done in succession, so that there may be a regular supply of cress. Those planted in May are fit to cut in August, and those planted in November are ready to gather in the spring.

4058. Culture in water-beds. Some market-gardeners who can command a small stream of water, grow the water-cress in beds sunk about a foot in a retentive soil, with a very gentle slope from one end to the other. Along the bottom of this bed, which may be of any convenient breadth and length, chalk or gravel is deposited, and the plants are inserted about six inches deep at any season. Then, according to the slope and length of the bed, dams are made six inches high across it, at intervals; so that when these dams are full, the water may rise not less than three inches on all the plants included in each. The water being
turned on will circulate from dam to dam; and the plants, if not allowed to run to flower, will afford abundance of young tops in all but the winter months. A stream of water, no larger than what will fill a pipe of one inch bore, will, if not absorbed by the soil, suffice to irrigate in this way an eighth of an acre. As some of the plants are apt to rot off in winter, the plantation should be laid dry two or three times a-year, and all weeds and decayed parts removed, and vacancies filled up. Cress grown in this way, however, is far inferior to that grown in a living-stream flowing over gravel or chalk.

4059. **Taking the crop.** The shoots are cut for market, not broken off, which is the usual mode of gathering the wild cress, and which latter practice is found to be very injurious to the plants in the beds. (Hort. Trans. iv. 540.)

4060. **The brook-lime** is a perennial plant, a native of Britain, and common in rivulets and wet ditches. It has a trailing or procumbent stem, furnished with smooth, dark-green, elliptical leaves, from the axillae of which proceed bunches of blue flowers in July.

4061. **Use.** The young tops and leaves are used as a salad, like the water-cress, with which it is often mixed, being milder, more succulent, and only slightly bitterish in taste. In Scotland the sprigs of brook-lime are brought to market under the name of *waterpurse,* and sold along with *wall-cresses* (well, or water-cresses).

4062. **Culture.** The same as for the water-cress.

4063. **The garden-rocket** is an annual plant, a native of Austria, and known in this country in 1573. The stem rises two feet high, is upright and branchy, and furnished with smooth, pulpy, cut and toothed leaves. When in flower in July, it has a strong peculiar smell, almost fetid. This plant is now neglected in Britain, but is still in use in several places on the continent.

4064. **Use.** The leaves and tender stalks are used as salad ingredients, and form an agreeable addition to cresses and mustard early in spring.

4065. **Culture.** Sow in a warm border early in February, and again in March and April for successive crops. Thin the plants after they have produced the first rough leaf to three or four inches asunder, and keep them clear of weeds. If a supply is desired throughout the year, monthly sowings may be made; and in autumn under frames.

4066. **To save seed.** Allow a few of the strongest plants of the spring sowing to come into flower; they will produce abundance of seeds in August.

4067. **The scurvy-grass** is a biennial plant, indigenous to most of our sea-shores, and, like the sea-pink (*Statice*), growing also on inland mountains. The root-leaves are round; those of the stem sinuated; the whole plant is low and spreading, seldom rising above a foot. The flowers are white, and appear in April and May.

4068. **Use.** The smaller leaves are occasionally used like the water-cress; and sometimes eaten between slices of bread and butter. The plant is also occasionally used medicinally.

4069. **Varieties.** A thick-leaved variety, called the Dutch scurvy-grass, is cultivated in some gardens.

4070. **Culture.** The plant may either be propagated from seed, or by dividing the roots. It delights in a sandy soil and a moist atmosphere, which it finds alike by the sea-shore and on lofty mountains. It will grow, however, almost any where, and is often found firmly established on old walls and ruins, sowing itself, and thus remaining many years. When to be raised from seed, sow about July. Plants from a spring sowing seldom prosper. Abercornisle says, "Sow in drills eight inches apart; and when the plants are up, thin them to six inches' distance; these thinned out, may be transplanted into new beds. In the following spring, the succulent leaves will be fit for use.

4071. **To save seed.** Leave some plants in flower in May, and they will ripen abundance of seed in July.

4072. **The burnet** is a hardy perennial plant, indigenous in Britain, and found in dry upland calcareous soils. The leaves are pinnate, and form a tuft next to the root; but are alternate on the stem: the leaflets are partly round-shaped, partly pointed, and much serrated on the edges. The stem rises fifteen inches high, and the flowers form small greenish heads tinged with purple in July.

4073. **Use.** Burnet-leaves are sometimes put into salads, and occasionally into soups, and they form a favorite herb for cool tankards. When slightly bruised, they smell like cucumber, and they have a somewhat warm taste. They continue green through the winter, when many other salad-plants are cut off, or in a state unfit for use. It was formerly in much greater repute than at present.
4074. Propagation and culture. The plant may be raised from seed; of which half an ounce will suffice for a bed three feet by four. It may either be sown in spring or early in autumn. It may also be very readily propagated by parting the roots early in spring. When the plants are of two or three inches growth, transplant into rows, or a bed, at six inches plant from plant. Cut down all flower-stalks not intended for seed.

4075. The wood-sorrel is an indigenous perennial plant, found in woods, and by hedge-sides, and in moist, shady situations. It has a scaly, bulbous, articulate root, and ternate, obcordate, hairy leaves. The flowers rise from the root singly, are of a pale flesh color, and appear in April and May.

4076. Use. The leaves form a very grateful addition to salading, and communicate an agreeable relish to dishes of mashed greens.

4077. Culture. The plant is readily propagated by dividing the roots, and may be planted in a moist shady situation in the earth. Here, by preventing the flower from coming into flower, and cropping off the herb of a part of the plantation two or three times in the season, a supply of fresh young leaves may be obtained from April to October.

4078. By small salads gardeners and cooks understand the small herbs, or very young plants, which are used in the seed-leaves; such as cress, mustard, radish, and rape; also the lamb-lettuce. Others, such as sorrel, are either pot-herbs or salad-herbs. Sometimes the white cabbage, lettuce, endive, and succory, are also sown, to be cut in the seed-leaf. The small salads are occasionally used by themselves, when there is a deficiency of the greater salad-plants, the lettuce, endive, celery, &c. But when both kinds can be had, they are in general combined.

4079. Culture. Sow very thick in drills, or on beds of very finely pulverised soil, watering in dry weather to accelerate germination and the succulence of the plants. Early in spring sow under glass, or in a warm sheltered situation, and in winter in pots and boxes to be placed in some of the forcing-houses, or in the stove; or sow in the borders of the forcing-houses, or in hot-beds or pits, &c. Observe, that a supply is wanted in most families throughout the year.

4080. Gathering. Cut off the seed-leaves and about half their foot-stalks, as soon as the former are expanded; some prefer letting small salading grow till one or two of the proper leaves appear, in which case it is of a stronger flavor.

Sect. VIII. Pot-herbs and Garnishings.

4081. Pot-herbs and garnishings require but a very small portion of the kitchen-garden, perhaps not above two or three poles, even in the largest, and with the exception of parsley, marigold, and Indian cress, they are rarely found in those of the cottage.

4082. The parsley is a hardy biennial, a native of Sardinia, and introduced in 1548. It is so common as to be naturalised in several places both of England and Scotland. The root-leaves are compound, and much curled in some varieties. The flowers are pale-yellow, and appear in June; they have usually one leaflet at the origin of the universal umbel; and an involucre of from six to eight short foliules, fine almost as hairs, to the partial umbel. It may be right to notice, that the poisonous plant called fool's parsley (*Æthusa Cynapium*), a common weed in rich garden-soils, has sometimes been mistaken for common parsley. They are very easily distinguished: the leaves of fool's parsley are of a darker green, of a different shape, and, instead of the peculiar parsley smell, have, when bruised, a disagreeable odor. When the flower-stem of the fool's parsley appears, the plant is at once distinguished by what is vulgarly called its beard, three long pendent leaflets of the involucrum. The timid may shun all risk of mistake by cultivating only the curled variety. This last, it may be remarked, makes the prettiest garnish.” (Nell, in Ed. Encyc.)

4083. Use. The leaves of the two first varieties are used as pot-herbs at all seasons of the year; also as a garnish. The third kind is esteemed for its large white carrot-shaped root, drawn in autumn and winter, likeparsneps, for the table; and occasionally to be used in medicine, being considered a remedy for the gravel.

4084. Varieties. These are —

| The common plain-leaved; seldom cultivated | The broad-leaved, or large-rooted Hamburgh; |
| Small-leaved; most esteemed | cultivated for its carrot-shaped root. |

4085. Culture of the pot-herb kinds. "One sowing in spring will mostly furnish young leaves all the year; though to answer a constant demand, many persons make successive sowings from February to May. Some also sow early in autumn for young parsley in winter and spring; but such a supply is better provided by cutting down established plants. Sow in a single drill, along the edge of any compartment, or occasionally in rows nine or twelve inches asunder. Draw small drills, something less than an inch deep; in which drop the seeds moderately thick, and cover a little above half an inch. The plants will come up in three or four weeks, and when two or three inches high, may be gathered as wanted, all the summer, winter, and following spring, till May, when they will go to seed. Have always a young crop sown timely in the spring, to succeed the declining old plants. In gathering pot-herb parsley, cut close and regular. In summer, when the plants grow rank, yielding more leaves than can be used, cut them in close to the bottom, and they will shoot up stocky in a regular close growth. Observe also to do
Purslane, Portulak, Dragioi, and Dillhraut, and they as very which or, when dwarf, autumn, by and sow in February, March, or early in April, in one or more beds; either in drills nine inches asunder, or broad-cast, and rake in. The plants should be thinned to nine inches' distance, to give room for proper growth in the roots; for use in August, September, October, and thence till the following spring. On the approach of frost, take up some roots, and preserve them in sand. A sowing may be made in the third week in June when transplanting roots are required.

To sow seed. "Permit some old plants to run to stalks in May; they will produce plenty of seed, ripening in July or August." (Abercrombie.)

The purslane is an annual plant, a native of South America, and introduced in 1552. It has a round, smooth, rather procumbent stem, and diffused branches; the leaves somewhat wedge-shaped and fleshy; the flowers, yellow and sessile, appear in June and July.

Use. The young shoots and succulent leaves are esteemed cooling, and are used in spring and summer as an ingredient in salads, and as pot-herbs and pickles. The plant was formerly much more in request than at present.

Varieties. There are two varieties of the P. oleracea cultivated, the green and the golden. The latter is by some considered as a distinct species (P. sativus). It has rather larger leaves, and is less succulent than the P. oleracea.

Culture. Both sorts are raised from seed, and for a bed four feet by four feet, sown either broadcast or in drills, nine inches apart, one eighth of an inch will suffice. "Each variety is somewhat tender; the green, which is usually preferred, is perhaps rather the hardest. An early crop may be sown in February or March, on a moderate hot-bed; the plants will require the sin of a gentle heat till the middle of May; when the seed may be sown in a warm border. If a continued succession is required, sow every month during summer, till August, or while the plant can be raised; generally in small drills, from three to six inches asunder. The plants will soon come up: they should remain where sown. In very dry hot weather, water thrice a week. The shoots may be gathered for use when they are from two to five inches in height, and are well furnished with leaves. Cut them off low, and the bottom part will soon sprout out again.

To sow seed. "Leave some of the first open-border plants to run; they will give ripe seed in autumn." (Abercrombie.)

The tarragon is a perennial plant, a native of Siberia, but cultivated in our gardens from the time of Gerard, in 1548. Its branched stem rises a foot and a half high, and has narrow leaves, green on both sides. The smell of the plant is fragrant, and its taste aromatic.

Use. The leaves and tender tips are used as an ingredient in pickles. A simple infusion of the plant in vinegar makes a pleasant fish sauce. In France it is employed, on account of its agreeable pungency, to correct the coldness of salad-herbs; it is also put in soups, and other compositions.

Culture. "Avoid planting tarragon in a wet tenacious soil; as in that case the root is apt to perish in June or July. The plants may be propagated in the spring, by seed; or, more expeditiously, by offset bottom slips, or sections of the root and top, planted in spring or autumn: also plentifully in summer, from June to August, by slips or cuttings of the spring stalks or branch shoots. The stems are to be planted in beds or borders from six to nine inches apart, and properly watered. They will quickly increase, and the branches are cut off, as for use the same year, to gather green, as wanted; and a portion may be dried and housed for winter. When the stems are running up for flower, if seed is not wanted to be saved, cut them down; which will force up fresh young shoots. It would be proper, towards the end of autumn, to transplant some few plants close under a south fence, to preserve them more effectually in winter, and cause an earlier production of young tops in spring."

To obtain green tarragon in winter. "Plant some stocky roots in a hot-bed, or in pots placed in a hot-house." (Abercrombie.)

The fennel is a perennial plant, naturalised in England, and found in chalky soils. The plant rises with finely cut leaves, and capillary leaflets, on a smooth, dark-green, branched, tubular stalk, to the height of five or six feet. On the summit are produced umbels of gold-colored flowers, in July and August. The whole plant is aromatic, and has long been an inmate of the garden.

Use. The tender stalks of common fennel are used in salads; the leaves boiled, enter into many fish sauces; and raw, are garnishes for several dishes. The blanched stalks of the variety called finochio are eaten with oil, vinegar, and pepper, as a cold salad, and they are likewise sometimes put into soups.

The varieties are —
Propagation. They are all raised from seed, of which half an ounce is sufficient for a seed-bed four feet by six feet. Sometimes also, they are raised from offsets from the old plants, where only a few are wanted. "Sow in the spring in light earth, either in drills from six to twelve inches apart, or broad-cast and raked in. When the plants are three or four inches high, thin or transplant a quantity fifteen inches asunder. As the roots of old plants divide into sideoffsets, these may be slipped off in spring, summer, or autumn, and planted a foot apart. They will produce immediate leaves for present supply, and in continuance; or for an immediate larger supply of leaves, you may procure some established full roots, and plant as above; let them be well watered."

Subsequent culture. "The same plants remain several years by the root: but as fennel sends up strong stems for seed in summer, these, or a part of them, should be cut down, to encourage a production of young leaves below, in succession. It is apt to spread more than is desirable, if suffered to seed. The swelling stems of the flowering plants, when some tolerable substance, should be earthed up on each side five or six inches to Blanch them white and tender. This will be effected in ten days or a fortnight; and by successive sowings, or cutting down plants during summer, successive crops of blanched stalks may be had from June to December."

To save seed. Permit some of the best stalks to shoot; they will produce large umbels of seed in autumn. (Abercrombie.)

The dill is a hardy biennial plant, a native of Spain, and introduced in 1570. The plant is of upright growth, somewhat similar to fennel, but smaller. It has finely divided leaves, and a slender single stem, bearing an umbel of flowers at top, which appear in June and July. The whole plant is powerfully aromatic.

Use. The leaves are used to heighten the relish of some vegetable pickles, particularly cucumbers; and also occasionally in soups and sauces. The whole herb is also used in medical preparations.

Culture. It is raised from seed, of which half an ounce is sufficient for a bed three feet by four feet. "Sow annually in February, March, or April, or occasionally in autumn, as soon as the seed is ripe, to come up stronger in the spring, in any open compartment; either in drills, six or twelve inches apart; or broad-cast, thinly, and raked in evenly. The plants should remain where raised; and may be thinned moderately, should they rise too thick. They will shoot up in stalks, with leaves and seed-umbels in summer and autumn, for use in proper season."

To save seed. "Leave some plants where raised: they will furnish plenty of seed in autumn. Or, from self-sown seeds, many plants rise spontaneously in the spring."

Chervil is an annual plant, a native of various parts of the continent of Europe, and sometimes observed naturalised in our gardens in England. The plant rises from a foot to near two feet high; the leaves are of a very delicate texture, three times divided, and the flowers, of a whitish color, appear in June. There is a variety cultivated in the Paris gardens, with beautifully frizzled leaves.

Use. The tender leaves are used in soups and salads; but are much less in demand now than formerly.

Culture. It is propagated from seed; and for a bed four feet by four, a quarter of an ounce is sufficient. "Sow a bed or two in August and September, as well to come in use at the end of the same autumn, as to stand for winter and spring. If a continued succession be required in spring and summer, begin to sow again in the last fortnight of February, and sow a portion every month till August, or twice a month in the midst of summer; as the plants of the spring and summer sowings soon rain up for seed. Sow the plants from six to nine inches apart, and earth in lightly; or sow occasionally broad-cast, and rake in evenly, just covering the seed. The plants are to remain where sown. When the leaves are two, three, or four inches in growth, they are proper for gathering. Cut them off close, they will shoot up again, and may be gathered in succession, though the plants of the spring and summer sowing soon spindle up into seed-stalks, ceasing to produce young leaves, which are the useful parts."

To save seed. "Leave some plants in the spring: they will shoot to stalks, and give ripe seed in July or August."

Horse-radish is a perennial plant, growing naturally in marshy places, and by the sides of ditches, in some parts of England. The leaves are very large, oblong, sometimes smooth, and at other times notched at the edges; on the stem they are sometimes deeply pinnatifid; the flowers are white, and appear in loose panicles in May and June. It has been long cultivated in gardens, and forms one of the most profitable articles raised by the market-gardener.
4112. Use. The root scraped into shreds is a well known accompaniment of English roast beef. It is also used in winter salads, in sauces, and sometimes eaten raw.

4113. Propagation and culture. The following excellent instructions are by Knight: "Horse-radish thrives under a sandy, loamy, that is not very dry in summer, nor inundated in winter; the situation must be open. During winter, trench the ground three feet deep, and in the following February procure your sets, in the choice of which take the strongest crowns or leading buds from old plants, cutting them about two inches long. Mark cet the ground in four-feet beds and one-foot alleys; then take the cone-like first bed nine inches of the top set, laying it upon the adjoining bed, after which take an opening at one end of the bed, in the common way of trenching, fifteen inches deep from the present surface; then level the bottom, upon which plant a row of sets across the bed, at nine inches apart each way; then in the next trench, the same width and depth, dig the earth into the first trench over the row of sets: thus proceeding trench after trench, to the end. Where more than the produce of one bed is required for the supply of the family for twelve months, the third bed is next to be planted, which treat as directed for the first, only observing to lay the earth on the fourth. Preserve, for any number of beds, which is not planted, a dwarfer annual crop may be grown. The plants must be kept clear from weeds during summer; and as soon as the leaves decay in autumn, let them be carefully raked off with a wooden-toothed rake; in the following February, eighteen inches of the earth of the unplanted bed must be laid as light as possible, and equally over the beds that are planted; then trench and plant the vacant beds exactly in the same manner as before directed. The following autumn, the first planted horse-radish may be taken up, by opening a trench at one end of the bed to the bottom of the roots, so that the sticks or roots of horse-radish may be taken up entire and sound, which for size and quality will be such as have not generally been seen. The following February the one-year-old crop will require additional earth as before directed, which must of course be taken from those beds which are now vacant, which, when done, if the ground appears poor, or unlikely to produce another vigorous crop, they must have a coat of manure." [Hort. Trans. v. 307.]

4114. Judd has also written on the culture of horse-radish (Hort. Trans. v. 302), and his practice, though very different from Knight's is also excellent, and perhaps preferable. Knight takes strong buds from old plants, while Judd takes about three inches of the top part of each stick or root, and then cuts clean off absolutely from the old root or crown, so that there are no appendages, such as a green bud. Judd trenches only two feet deep, and if he applies manure, put it in the very bottom of the trench; "for if not so done, the horseradish, which always puts out some side roots, would send out such large side roots from the main root, in search of the dung lying contiguous, as materially to injure the crop. In planting, dibble first bed nine inches of the top set, laying it upon the adjoining bed, after which take an opening at one end of the bed, in the common way of trenching, fifteen inches deep from the present surface; then level the bottom, upon which plant a row of sets across the bed, at nine inches apart each way; then in the next trench, the same width and depth, dig the earth into the first trench over the row of sets: thus proceeding trench after trench, to the end. Where more than the produce of one bed is required for the supply of the family for twelve months, the third bed is next to be planted, which treat as directed for the first, only observing to lay the earth on the fourth. Preserve, for any number of beds, which is not planted, a dwarfer annual crop may be grown. The plants must be kept clear from weeds during summer; and as soon as the leaves decay in autumn, let them be carefully raked off with a wooden-toothed rake; in the following February, eighteen inches of the earth of the unplanted bed must be laid as light as possible, and equally over the beds that are planted; then trench and plant the vacant beds exactly in the same manner as before directed. The following autumn, the first planted horse-radish may be taken up, by opening a trench at one end of the bed to the bottom of the roots, so that the sticks or roots of horse-radish may be taken up entire and sound, which for size and quality will be such as have not generally been seen. The following February the one-year-old crop will require additional earth as before directed, which must of course be taken from those beds which are now vacant, which, when done, if the ground appears poor, or unlikely to produce another vigorous crop, they must have a coat of manure." [Hort. Trans. v. 302.]

4117. Use. The flowers and young leaves are frequently eaten in salads; they have a warm taste, like the common cress, thence the name of nasturtium. The flowers are also used as a garnish to dishes, in which they form a brilliant contrast with the flowers of borage. The berries are gathered green and pickled, in which state they form an excellent substitute for capers.

4118. Varieties: —

There is a variety with double flowers, which is propagated by cuttings, and requires to be treated as a greenhouse plant. The flowers are preferable for garnishing.

There is also a variety of this species with double flowers, propagated by cuttings, and preserved through the winter underground; but, like the double variety of T. rutab, it is more ornamental than useful.

4119. Culture. The single varieties of both sorts are raised from seed, of which one ounce will sow twenty-five feet of drill. The plants will thrive in almost any soil, but a light fresh soil is best, as less likely to make the plants grow rank and luxuriant, and produce few berries, which one that is rich is apt to do. Care must be taken to select good sound seed, berries of the last year, for those of greater age will not grow at all, or not freely and regularly. "Sow in March or April, or not later than the beginning of May, in one drill, of one, two, or three rows, for a moderate family. Either allow the large sort a situation in a single row, near a vacant fence, trellis, or wall, on which the runners may be trained; or divide an open compartment into rows, three or four feet asunder, to admit sticks for their support. Form double rows of hills, by its planters, from the seeds two or three inches apart, with three or four evenly. When the plants begin to advance in runners, let them be trained to a fence or trellis. It is generally necessary, at first, to conduct the main runners, but they will afterwards climb unassisted." [Hort. Trans. v. 303.]

4120. To save seed. "Permit a sufficiency of the berries to remain till mature. In August and September, gather them as they ripen; spread them to dry and harden; then put them up for sowing next year." [Abercrombie.]

4122. The pot-marigold is an annual plant, a native of France and Spain, and known in this country since 1575. It has a short divergenced stem, dividing into numerous branches, from one to two feet in height, and furnished with blunt lanceolate leaves. The yellow flowers proceed from the ends of the branches, and last from June till killed by the frost. It is one of the oldest and best known inhabitants of our gardens. "Its flowers," Gerrard observes, "having been formerly in much reputation as comforters of the heart." Though little faith is now placed in its virtues, it still keeps its place in most cottage gardens, both in England and Scotland, though rarely applied to any culinary purpose.

4123. Use. Marshalse observes, that "the flower is a valuable ingredient in broths and soups, however much it may have got into disuse." The dried flowers are also used in domestic medicine.

4124. The varieties are —

The single orange-flowered; most aromatic and proper for keeping | The chilting or proliferous; sends out small flowers from the
The single lemon-flowered; rather less aromatic | margins of the calyx of the large central flowers, cul-
The double flowered of both varieties | tivated chiefly for ornament.

4125. Culture. Sow in February, March, or April, and for a seed-bed four feet by four feet, sown in drills a foot asunder, a quarter of an ounce will suffice; "or you may deposit the seed in autumn (Sep-
tember), to have it come up forwarder in the spring, though the spring sowing will come up in very good
time. Sow on a light dry soil, either in drills a foot asunder, or broad-cast; and rake in the seed. When
the plants are up two or three inches in growth, thin them to about twelve or fifteen inches asunder, or
they may be transplanted with that interval. They will grow freely in either method, and come into
flower in the following May or June, and continue flowering in plentiful succession throughout summer and
autumn; to be cut for use as wanted. A store for winter should be gathered when in full flower, spread
to dry out of the sun, and afterwards put up in paper bags."

4126. To save seed. "The flowers, as far as they are left to run, will in autumn produce a competency." (Abercrombie.)

4127. The borage is an annual, and sometimes a biennial plant, with the lower leaves oblong, alternate, and spread on the ground; the flower-stem rises nearly two feet high;
and, with the leaves, is rough with white bristly hairs. The light-blue flowers make a
beautiful appearance, and are produced for several months in succession, beginning with
May. It is a native, or naturalised in several parts of Britain.

4128. Use. The young leaves and tender tops are used occasionally as salads, and to
furnish a boiled dish in summer and autumn. "The plant was formerly in high estimation
as a cordial herb for driving away sorrow; but "very light surely," says Sir J. E. Smith,
"were those sorrows that would be so driven away." The spikes of the flowers form an
ingredient in negus and cool tankards, and the blossoms are occasionally employed
as a garnish. The juice of the plant affords niter, and the withered stalks have been
observed to burn like match-paper.

4129. Course of culture. It is raised from seed, and for a bed four feet and a half by six feet, one ounce
is requisite. "Sow every year in the spring, any time in February or March, till May, &c. for summer
supply; and in any of the summer months, for young borage in autumn, as the plants of the spring and
early summer sowings soon run up to stalks in the same year; and in July or August and September, to
furnish young leafy plants for winter and following spring. A small crop of each sowing will be sufficient
for the supply of a family. This herb loves a dry soil. Sow either broad-cast, and raked in, or in small
drills six to twelve inches asunder. Where the plants rise too close, thin them to that distance. Although
this herb will grow when transplanted, it prospers best when it remains where sown. Where the young
leafy tops and flower-spikes are in demand, permit the stem to run up."

4130. To save seed. "Leave some of the plants which first run: they will produce plenty of seed
in autumn; and from self-sown seeds many young plants will come up spontaneously." (Abercrombie.)

SEC. IX. Sweet Herbs.

4131. Of sweet herbs, one or two kinds, as the lavender, peppermint, and some other
mints, are extensively cultivated by market-gardeners for the druggists; but a very few
square yards of the private kitchen-garden will suffice to cultivate as much of each as is
ever wanted by any family. The sage, thyme, mint, and tansy, appear in single plants
in the border of the cottage's garden.

4132. Of thyme there are two species cultivated for culinary purposes, the common
and the lemon thyme.

4133. Common or garden thyme is the Thymus vulgaris, L.; a low evergreen under-
shrub, a native of Spain and Italy, and cultivated in this country since 1548, and prob-
ably long before. It seldom rises above a foot high, has smaller flowers than the
common wild thyme, and is more delicate in its flavor. There are two varieties, the
broad and the narrow leaved, besides the variegated, grown for ornament.
4134. Lemon thyme is the T. citriodorus, P. S.; a very low evergreen shrub, trailing and seldom rising above four or six inches in height. It is readily distinguished from the former, and from wild thyme, of which it has generally been considered as a variety, by its strong smell of lemons, as the trivial name imports.

4135. Use. The young leaves and tops are used in soups, stuffings, and sauces. For these purposes, the broad-leaved common is generally preferred; but the flavor of the yellow is much liked in peculiar dishes.

4136. Culture. "To raise the plant from seed is the general and most eligible method. It is occasion-ally multiplied by parting of the roots of stocky close plants, and by slips of the young shoots."

4137. By seed. "Sow in March or April in a bed or border of light fine earth, either broadcast scattered, or sown in closely, in a hotbed of light fine earth, six inches asunder: the young plants may either remain, or be transplanted in the summer, when two or three inches high. A portion may be drilled, for an edging to a border. Give occasional light waterings in dry warm weather, both before and after the plants are up. As soon as they are from three to five inches in growth, in June or July, taking the opportunity of rain, thin some out, and plant six inches asunder, and water at planting. Others may be planted in a single row to form an edging to a border, either set close to form at once a full edging, or as far as three inches apart. Seeding thus treated will come in for use the same year. Those who raise considerable supplies of thyme for the markets, usually sow large portions the latter part of April, and transplant them in spring and autumn; they are drawn in root and top to-gether, at different seasons, as wanted; it is then tied in small bunches for market. Some persons also transplant considerable proportions in spring and summer, to six, ten, or twelve inches' distance, to form a stocky full growth, to be drawn off in large bushy plants."

4138. By offsets. "Thyme is also propagated by slips of the branchy shoots in the spring, or early in autumn; but more effectually by sections of the stool, top and root together, or by removing rooted branches. To make branches quickly root, loosen the mould about any established bushy plants, in spring or summer, and lay some fresh earth a small depth upon the spreading shoots: they will all be well rooted the same year for planting off. Plant in light rich earth: shade and water till rooted. In autumn, to provide against the effects of frost on exotic evergreens, dry and house a store for winter; either cutting the tops, or drawing entire plants."

4139. By seed. "It is produced abundantly, and ripens in summer and autumn. Gather the seedspikes, spread them upon a cloth to dry; rub out clean, and put the seeds up for sowing the following year."

(Abercrombic.)

4140. The sage is an evergreen under-shrub, a native of the south of Europe, and mentioned by Gerard, in 1597, as an inhabitant of our gardens. It rises about two feet high, with wrinkled, green, cinereous leaves, white, or tinged with white or dusky purple. The flowers are terminal, in long spikes, of a blue color, and appear in June and July.

4141. Use. The leaves are used in stuffings and sauces for many kinds of lus- cious and strong meats; as well as to improve the flavor of various articles of cookery. The decoction called sage-tea is usually made from one variety, the small-leaved green, or sage of virtue; but any of the others are equally fit for this purpose.

4142. Varieties. These are —

| The common, or red | The green | The small-leaved green, or sage of virtue | The broad-leaved, or balsamic.

4143. Estimate of sorts. "The red is the principal sort in culinary use, having the most agreeable and fullest flavor; the green is next in estimation with the cook: but the small-leaved is generally preferred to those to eat as a true herb, and for decoctions, while the broad-leaved balsamic species is the most ef-ficacious in a medical way, and is also a tea-herb. However, any of the sorts may be occasionally used for those alternate purposes."

4144. Culture. "All the varieties may be propagated by slips or cuttings of the young shoots, taken from March to June; but most successfully in May and June, by detaching the young shoots of the same year. The outward shoots are to be preferred; slip or cut them off five or six inches long, stripping off the under leaves, and preserving the top leaves entire: plant them in a shady border, six inches asunder, inserting them a little deeper than they were grown in the bed, to cause the soil freely, especially the young shoots planted in May and June. In the advancing growth, if they spindle up in flower-stalks, pinch or cut that part down, so that the plants may shoot out full and stocky from the bottom in close bushy growth for use the same year. In gathering sage for use, cut or slip off the young side and top shoots neatly; and be careful not to stub too close, especially towards winter, and during that season. In July and the rest of summer, it is usual to gather some of young top growth to dry for winter. Keep the plants in regular bushes by cutting away disorderly growths, and the decayed flower-stalks in autumn. Keep them clear of weeds; and sometimes loosen the earth between and about the plants, with a hoe, garden-trowel, &c. Make no fresh plantation once in two, three, or four years, or as may be necessary by the plants becoming naked, stubby, and dwindling."

(Abercrombic.)

4145. The clary is a hardy biennial, a native of Italy, introduced in this country in 1562. The lower leaves are very large, the stem is about two feet high, clammy to the feel; the flowers are in loose, terminating spikes, composing whorls, and of a pale-blue colour.

4146. Use. The leaves are sometimes used in soups, though some dislike its scent. Its flowers are used for a fermented wine, and the whole plant is, like sage, esteemed medicinal.

4147. Culture. Clary is raised from seed, and sometimes from cuttings and slips. A small bed will supply most families; and, if raised from seed, a quarter of an ounce will suffice for a seed-bed to be trans-planted from two feet by two. Sow in the last fortnight of March, or the course of April, in any bed or border, and a little细细, and rake in the seed. When the plants are advanced two or three inches, transplant a portion of the strongest from twelve to eighteen inches apart, to allow competent room for the
leaves to spread into full growth, when they will be fit for use the same year, and in continuation through water until the following spring and summer.

4148. To save seed. In the spring, allow some old plants to run up into stalk; these will yield ripe seed in autumn.

**SUBSECTION 4. Mint. — Mentha, L. Didymos, L. and Labiate, J. Menthe, Fr.; Münze, Ger.; and Erba Santa Maria, Ital. (fig. 472).**

4149. Of mint there are several species cultivated in gardens; all of them indigenous perennials. The principal are —

4150. The peppermint (M. piperita, L.), (Eng. Bot. 687.) (a). This species may readily be distinguished by its subcamphorated odor, and blackish-purple flowers, which appear in August and September. It is found in watery places.

4151. Use. Almost entirely for distillation, for which it is extensively cultivated in low, rich, soft, marshy lands, especially such as can be irrigated or flooded.

4152. *The spearmint (M. viridis, L.), (Eng. Bot. 2494.)* (b). This sort rises from two to three feet high, with sessile, lanceolate, naked leaves; the whole plant has a reddish-green hue; is occasionally found in marshy situations, and flowers in August. There is a narrow and a broad-leaved variety.

4153. Use. The young leaves and tops are used in spring salads, and form an ingredient in soups; they are also employed to give flavor to certain dishes, as peas, &c., being boiled for a time, and then withdrawn in the manner of garlic.

4154. *The pennyroyal-mint (M. pulegrium, L.), (Eng. Bot. 1206.)* (c) Poulot, Fr.; Poley, Ger.; and Paleggio, Ital.; is a trailing plant with small, smooth, ovate leaves. It is indigenous in watery pastures, and places subject to inundations. It flowers in September.

4155. Use. In different branches of cookery, and also for distilling pennyroyal-water.

4156. Culture. All "the species are raised by the same methods, viz. by parting the roots, by offset young plants, and by cuttings of the stalks." By the roots. This is performed in spring or autumn. Having some full roots from any established beds, divide them as expeditiously; and drawing drills with a hoe, about two inches deep, and six inches asunder, place the roots in the drills, moderately close, and earth them over to an equal depth. By offsets in the spring. Procure these from established plants, and subdivide them, in rows, six inches asunder. By cuttings of the young stalks in May, June, or advanced summer. Taking the opportunity of showery weather, cut them into lengths of five or six inches; and plant the cuttings by dibble, six inches apart, inserted half way into the earth.

4157. Soil. Spearmint and peppermint like a moist soil; pennyroyal a strong loam.

4158. Subsequent culture. "Prepared in any of the above methods, the plants set in spring or summer will come into use the same year. Water new plants till they take root. Keep them clean from weeds. At the end of autumn, cut away any remaining stems; at which season, or in spring, spread a little loose earth thinly over the beds."

4159. Taking the crop. "For culinary use, or salads, gather both when the young green tops are from one inch to six inches in length, and in their advanced growth, throughout the summer. When nearly full grown in June, July, or August, or beginning to flower, gather a store for winter. Spread the heads thinly in some dry place, shaded from the sun, to be well dried; then, tied in bunches, house the store. When designed for distilling, let them attain full growth, coming into flower; then cut, and use the heads immediately. The peppermint, being principally used for distilling, and such of the pennyroyal as is wanted for the same purpose, should stand till they begin to flower; being then in highest perfection. Cut in dry weather and tie in bunches, and carry under cover, ready for immediate use. Cut full-grown stalks close to the bottom."

4160. New plantation. "All the species continue by the roots many years; but when the plants shoot dwindling, or weakly, make a fresh plantation in time."

4161. Forcing spear mint. "Mint, in a young green state, may be obtained all winter, and early in spring, by planting some roots in a gentle hot-bed, or in pots or shallow pans, to be plunged therein. Plant the roots pretty thickly, and earth over an inch and a half deep; or some roots, thus planted in pots, placed in a sheltered place, every three weeks, as forced roots soon decay. In order to have young leaves and tops all the summer, cut down some advanced stalks every month, when new shoots will be thrown up; and to have dried balm for the winter, permit others to complete their growth into blossom. These last are to be cut as soon as the dew is off in the morning, for in the afternoon, and especially during bright sunshine, the odor of the plant is found to be much diminished. Dry the crop thus gathered in the shade, and afterwards keep it in small bundles, compactly pressed down, and covered with white paper. By the common mode of hanging up mint and other herbs in the autumn, soil or earth may be absorbed; the mint, unless a travelling root, the bed soon becomes covered, so as not to admit of further culture; hence, after four or five years' standing, a fresh plantation will require to be made."

**SUBSECTION 5. Marjoram. — Origanum, L. Didymos, L. and Labiate, J. Marjolaine, Fr.; Marjorana, Ger.; and Maggiolana, Ital.**

4162. Of marjoram four different species are cultivated; the pot, sweet, winter, and common.

4163. *Pot-marjoram* is the O. Onites, L. (Bocc. Mus. t. 38.). A hardy perennial under-shrub, a native of Sicily, introduced in 1759. The stem rises more than a foot high,
and is covered with spreading hairs; the leaves are small and acute, almost sessile, and tomentose on both sides. Though hardy enough to withstand our winters, it seldom ripens its seeds in this country. It is in flower from July to November, and is propagated from seed, but chiefly from rooted slips.

4164. *Satureja montana* is the *O. Marjorana*, *L.* (Moris. s. 11. t. 3. f. 1.) a hardy biennial, a native of Portugal, and introduced in 1575. It resembles the *O. Onites*, but the leaves have distinct petioles, and the flowers, which appear in June and July, are collected in small close heads; and hence is often called knotted marjoram. As the seed seldom ripens in this country, it is generally procured from France. When in blossom, the herb is cut over, and dried for winter use, so that a sowing requires to be made every year.

4165. The winter *sweet marjoram* is the *O. Heracleoticum*, *L.* (Eng. Bot. 1143.) a hardy perennial, a native of Britain, and found under thickets and copses on chalky soils. It bears a considerable resemblance to the last-named species. The flowers arise in subrotund panicles, in smooth clustered spikes, of a reddish color, in July and August. This species is only used in cookery in default of one of the others.

4167. Use. All the species, but especially the three first, are aromatic, of sweet flavor, much used as relishing herbs in soups, broths, stuffings, &c. The young tender tops and leaves together are used in summer in a green state; and they are dried for winter.

4168. Culture. The three first species prefer a light dry soil; the other, a calcareous soil and shady situation. Though the *O. Marjorana*, or sweet marjoram, be a biennial in its native country, and here, when it receives the aid of a green-house through the winter, yet, in the open garden, it requires to be treated as an annual, and sown and reaped the same year. For a seed-bed three feet by three feet, a quarter of an ounce of seed is sufficient. Sow in April on a compartment of light earth, either in small drills, or broad-cast; or sow a portion in a hot-bed, if requisite to have a small crop forwarded. When the plants are one, two, or three inches high, thin the seed-beds; and plant those thinned out in a final bed, six inches apart, giving water; or, where larger supplies are required, some may remain thick where sown, to be drawn off by the root as wanted. The pot, winter, and common marjoram may be propagated from offsets by parting the roots in spring and autumn. Plant in rows or in beds, allowing a square foot for each plant.

4169. Gather the tops of all the sorts as wanted for summer use; and when in full blossom, in July or August, for preservation through the winter.

4170. Of *savory* two species are cultivated, the winter and summer savory.

4171. *Winter savory* is the *S. Montana*, *L.* (Sob. Hort. 3. t. 64.) a hardy under-shrub, a native of the south of France and Italy, and known in this country since 1562. The shoots are furnished with two narrow stiff leaves, an inch long, placed opposite at each joint, and from the base of these a few small leaves proceed in clusters. It produces whisht flowers in May and June.

4172. *Summer savory* is the *S. Hortensis* (Lam. Ill. ii. 504. f. 1.) a hardy annual, a native of Italy, and known in this country since 1562. The branches are slender, erect, and about a foot high; leaves opposite, and about an inch in length. It flowers in June and July.

4173. Culture. “The perennial is generally propagated by slips, or cuttings, of the young side shoots, in April, May, June, or July; planted in a shady border, and watered; also by dividing the bottom off-set rooted shoots, the root and top-part together, planted as above. When the plants are a little advanced in branchy top growth, they may be transplanted: set some in single plants, a foot apart; others, to form a close edging. Keep the ground clear of weeds: in spring and autumn loosen the earth a little about the plants, and trim off decayed and regular parts. This herb may also be occasionally raised from seed in the spring, as directed below, for the summer savory. It continues useful summer and winter; and some may be gathered, when of full growth, in autumn, to dry for winter use. The annual is always raised from seed. In March or April, sow either in small drills, nine by six inches apart; or, on the smooth surface, and rake in lightly. The plants may either remain, to be thinned, or some may be transplanted in June, nine by six inches asunder. This herb comes in for gathering from June until October. When a store is to be dried, draw it by the roots.” (Abercromb.)

4174. *Basil* two species are cultivated as culinary aromatics. The sweet, or larger *basil*, is the *O. Basilicum*, *L.* (Blackw. t. 104.) a tender annual plant, highly aromatic, rising from six to twelve or fifteen inches high, and thickly covered with small oval leaves. It produces small white flowers in June and July; is a native of the East Indies, and was introduced to this country in 1548.

4175. *The bush, or least basil*, is the *O. Minimum*, *L.* (Schl. Hand. 2. t. 166.) an annual aromatic plant, a sort of diminutive of the other, forming a round orbicular bushy
head, not half the size of the larger basil. It is a native of the East Indies, flowers in June and July, and was introduced to this country in 1578.

4176. Use. The leaves and small bracthe, or leafy tops, are the parts gathered; and on account of their strong flavor of cloves, they are often used in highly seasoned dishes. A few leaves are sometimes introduced into salad, and not unfrequently into soups.

4177. Culture. Both species are raised from seed, and for a seed-bed of three feet by one and a half, to furnish plants for a final plantation four feet by twelve, a quarter of an ounce will be sufficient. Sow on a hot-bed in the end of March, and plant out in a warm border of rich soil, the larger at eight or ten inches every way, and the lesser at six or eight inches square. Sometimes both sorts are sown in the open border; but so near two thirds into the ground: wait until the plants are large enough to plant. In the small tufts, or single plants, with balls attached; by which they receive no check, and if watered after planting, and in dry weather, will soon produce abundance of tops.

4178. Seed can only be saved in England in warm dry seasons, and under the most favorable circumstances of situation and proximity. In general it is procured by the seedmen from Italy.

4179. The rosemary is a hardy under-shrub, a native of the south of Europe, introduced in, or before, 1548. The plant is evergreen, rising sometimes six or eight feet high, though rarely. The leaves are sessile, linear, dark-green above, and greyish or whitish beneath; the blossoms are of a pale-blue color. The whole plant is highly aromatic.

4180. Use. The flowers and calyces form a principal ingredient in the distillation of Hungary water. Infusions of the leaves are made in some drinks. Sprigs of rosemary are used as a garnish; and were given in Shakespear’s time as tokens of remembrance: “There’s rosemary; that’s for remembrance,” says the distracted Ophelia. In some parts of the west of England and in Wales, the sprigs are still distributed to the guests at funerals, and often thrown into the grave upon the coffin of the deceased.

4181. Varieties. These are —

| The green, or common | The gold-striped. | The silver-striped. |

4182. Culture. “The green is hardest as a plant, and is the sort generally used. The finest plants are raised from seed. Sow either broad-cast or in small drills, six inches apart. The green is also raised by planting slips or cuttings of the young shoots in spring and summer, in a shady border. Let these be taken off six, or seven inches long, detaching the under-leaves. Set them in a row from six to twelve inches apart, and occasionally afterwards, till they have struck. The plants will be strong and well rooted by autumn, when they should be transplanted at plant distances. A light sandy soil assists exotic evergreens, that retain some of their original delicacy, to stand the winter; partly by preventing them from growing too luxuriantly, and partly by not being a conductor of frost. In their final situations, train the plants, either with a bushy head, of moderate growth; or, if near a fence, in a fan-like order. The striped sort may be propagated as above; or with most success, by layers of the young wood, as it is not so free to grow from cuttings. Being a little tender, it must be planted in a warm situation. It is retained chiefly as ornamental, on account of the variegation of its leaves. Rosemary is of several years duration, continuing in full foliage at all seasons where the exposure is not too severe.” (Abbercornic.)

4183. The lavender is a hardy under-shrub, a native of the south of Europe, and introduced in 1638. The plant rises from two to four feet high, with hoary linear leaves, slightly rolled back at the edges; the flowers form terminating spikes, of a blue color, and appear from July to September. The leaves and flower are powerfully aromatic.

4184. Use. It is rather a medicinal plant than one used in cookery; though a few plants are kept in every garden. Imitation scent-bottles are made by the ladies of the fragrant spikes. They are also put in paper-bags, and placed among linens to perfume them. Lavender-water, a well known perfume, is distilled from the flowers; for which purpose the plant is extensively cultivated in different places, but more especially at Mitcham in Surrey, and Maidenhead in Berkshire.

4185. Varieties. The narrow-leaved and the broad-leaved, both equally good.

4186. Propagation and culture. “It is propagated by cuttings and slips like rosemary; it likes a dry soil, and may be planted either in distinct plants two feet asunder, or to form a sort of hedge-row, in one or more lines, especially where large supplies of flowers are required for distilling. The plants will advance in a close branchy growth, from a foot and a half to two feet high, or more; and, when established, will produce plenty of flowers in July and August: gather them while in perfection, cutting the spikes off close to the stem. Then give the plants occasional trimming, taking off the gross and rampant shoots of the year; and when the flowers are half open. Neat observance in this will observe the flowers in plenty. If lavender be planted in a dry gravelly, or poor soil, its flowers have a powerful odor, and the severity of our winters has little effect on it; while in a rich garden-soil, although it grows strongly, it is apt to be killed, and the flowers have less perfume.”

4187. The tansy is a perennial plant, growing in many parts of Britain on the sandy banks of rivers. The stem rises to the height of two or three feet in its wild state, richly furnished with deep-green finely divided leaves; the flowers are yellow, and appear in terminating corymb in July and August. The leaves and flowers are aromatic.
4188. Use. The young leaves are shredded down and employed to give color and flavor to puddings; they are also used in omelets and other cakes, and were formerly in much repute as a vermifuge.

4189. Varieties. These are, the common; the curled, generally preferred; and the variegated, cultivated chiefly for ornament.

4190. Culture. Tansy may be propagated in spring or autumn by rooted slips, or by dividing the roots into several sets: plant them in any compartment of the kitchen or physic garden, from twelve to eighteen inches asunder. The plant continues for several years, producing abundant tufts of leaves annually. As they run up in strong stalks in summer, these should be cut down to encourage a production of young leaves low on the stem.

4191. To have young tansy in winter. Plant some roots either in a hot-bed or in pots placed therein, or in a pinery or forcing-house, at any time from November to March. (Abercrombic.)

4192. The costmary is a hardy perennial plant, a native of Italy, and introduced in this country in 1568. The lower leaves are large, ovate, of a greyish color, and on long foot-stalks; the stems rise two or three feet high; they are furnished with leaves of the same shape, but smaller and sessile. The flowers are of a deep yellow color, and appear in corymbs in August and September. In indifferent seasons, or in cold situations, they scarcely expand, and the seeds very seldom come to maturity in this country. The whole plant has a peculiarly agreeable odor, and its name, costmary, intimates that it is the costus, or aromatic plant of the Virgin. There is a variety with deep-cut, hoary leaves, but it is less fragrant than the other.

4193. Use. In France it is used in salads; and was formerly put into ale and negus; and hence the name of alecost. In this country, at present, it is but little used in the kitchen.

4194. Propagation and culture. It is a travelling-rooted plant, and readily propagated by division after the flowering season, or in spring. It delights in a dry soil, and a plantation once made will remain good for several years.

Sect. X. Plants used in Tarts, Confectionary, and Domestic Medicine.

4195. Of confectionary plants, excepting the species of rhubarb used as a substitute for, or addition to, gooseberries, this class occupies only a few yards of the largest kitchen-garden. Almost the only species worthy of introduction in that of the cottage, unless we except the chamomile, is the rhubarb.

4196. Of rhubarb there are three species in cultivation, the rhaponticum, hybridum, and palmatum, all perennials.

4197. Rheum Rhaponticum, L. (Sabb. Hort. i. t. 34.) is a native of Asia, and was introduced in 1573. The leaves are blunt and smooth, veins reddish, somewhat hairy underneath; petioles grooved above and rounded at the edge. This species has been longest in cultivation.

4198. R. hybridum, L. (Murr. Com. Gott. t. 1.) is also a native of Asia, introduced in 1778. The leaves are large, somewhat cordate, smooth, and of a light green. When under good cultivation, they often measure four or five feet in length, the foot-stalk included. This sort was first introduced as a culinary rhubarb by Dickson, V.P.H.S., about twenty years ago, and is esteemed more succulent than the R. Rhaponticum.

4199. R. palmatum, L. (Mill. Ic. 2. t. 218.) is a native of Tartary, distinguished from all the others by its elegant palmate leaves. It has been known in this country since 1758, and is generally considered as the true Turkey or Russian rhubarb.

4200. Use. The two first species are cultivated entirely, and the third in gardens, principally for the petioles of the root-leaves, which are peeled, cut down, and formed into tarts and pies in the manner of apples and gooseberries. The R. hybridum affords the most abundant and succulent supply for this purpose.

4201. Propagation and culture. All the sorts may be raised either from seed or by dividing the roots. If from seed, which is the best mode, sow in light deep earth in spring; and the plants, if kept eight or nine inches asunder, will be fit for transplanting in autumn, and for use next spring. When the roots are divided, care must be had to retain a bud on the crown of each section: they may be planted where they are finally to remain. When a plantation is to be made, the ground, which should be light and rather sandy, but well manured, should be trenched three spits, or as deep as the sub-soil will admit, adding a good manuring of well-rotted hot-bed dung. Then plant in rows three feet wide by two feet, in the rows for the R. rhaponticum and palmatum, and five feet wide by three feet, in the rows for the R. hybridum. No other culture is required than keeping the ground free of weeds, occasionally stirring it during summer with a three-pronged fork, and adding a dressing of well rotted manure every autumn or spring, stirring the earth as deep as possible. Such a plantation will continue good many years. Some never allow the flower-stalks to produce flowers; and others cut them over as soon as they have done flowering, to prevent the plants from being exhausted by the production of seeds. The former seems the
preferred method, as the flower-stalks of plants cannot, like the leaves, be considered as preparing a reserve of nourishment for the roots.

4202. Blanching. The advantages of blanching the stalks of rhubarb for culinary purposes have been pointed out by T. Harc, Esq. (Hort. Trans. vol. ii.) "These are twofold, namely, the desirable qualities of improved appearance and flavor, and saving in the labor of forcing the roots to the palate, since the leaf-stalks, when blanched, are infinitely less harsh than those grown under the full influence of light in an open situation." It may either be blanched by earthing up the roots early in spring, or earthen pots or covers may be used, as in blanching sea-kale.

4203. To force rhubarb. Two methods are described in the Hort. Trans. vol. iii. The first is by Judd, of Edmonton, who states, that his first attempt was made by covering plants of the rhubarb hybridum with common garden-pots, number twelves, having their holes stopped. These were covered with fermenting dung; and the plants came very fine and quickly; but were much broken by the sides and tops of the pots. "After it was all well up, the dung and pots were entirely taken off, and large hand-glasses were substituted in their stead, thickly covered with mats every night, and in dull weather. This process I found greatly to improve their flavor, and it gave me a regular supply till that in the open air was ready for use. The following year I had large pots made on purpose, without holes, but these broke the shoots almost as much as the first, for this sort of rhubarb grows so very luxuriantly, that it is impatient of such confinement."

He afterwards enclosed and covered his bed with open frame-work, around and on which, he placed the dung, and with this treatment, he says, "the rhubarb has come up very regularly, of excellent quality, and wants far less attention than was required by my former method; for the frame-work renders hand-glasses, or any other cover, unnecessary. Care should be taken to lay the dung in such a manner that the top may be partly or wholly taken off at any time for the purpose of gathering or examination, without disturbing the sides. That this is a superior method of forcing the rhubarb hybridum, this year's experience has satisfied me; but still the forcing by pots will answer very well for any of the smaller growing species. I have never found any difference between using dung fresh from the stable, and that which had undergone fermentation, provided it was not suffered to heat violently after its application to the frame. I do not permit the internal heat of the hollow space, above the plants, to rise above 60°, between 55° and 60° being the proper medium. To those who dislike the trouble of either frames or pots, it may be useful to know that rhubarb will come in much quicker, by being covered about six inches thick, with light litter; care should be taken, in putting it on, and removing it, that no injury be done to the plants."

4204. Knight has forced the rhubarb, and gives the following rationale of the principles on which his practice is founded. "The root of every perennial herbaceous plant contains within itself, during winter, all the organizable matter, which it expends in the spring in the formation of its first foliage and flower-stems; and it requires neither food nor light to enable it to protrude these, but simply heat and water: and if the root be removed entire, as soon as its leaves become lifeless, it will be found to vegetate, after being replanted, as strongly as it would have done, if it had retained its first position. These circumstances led me, in the last winter, to dig up the roots of many plants of the common rhubarb (which I had raised from cuttings in the preceding spring), and to place them in a few large and deep pots, each pot being made of twelve or more leaves of within. Some of them were entirely planted with the interspaces between the roots, the tops of which were so placed as to be level with each other, and about an inch below the surface of the mould in the pots, which were covered with other pots of the same size, inverted upon them: being then placed in a vinery (in a situation where nothing else could be made to thrive on account of want of light), and being copiously supplied with water, the plants vegetated rapidly and strongly; and from each pot I obtained three successive crops, the leaf-stalks of the two first being crowded so closely as nearly to touch each other over the whole surface of the pots. As soon as the third crop of leaves was broken off, and a change of roots became necessary, those taken from the pots were planted in the open ground, their tops being covered about an inch deep with mould, and I have reason to believe, from present appearances, that they will live and recover strength, if given a year of rest to be fit for forcing again. Should they, however, perish, it is of very little consequence; as year-old roots, raised from cuttings or even from seeds, sown in autumn in rich soil, will be found sufficiently strong for use. The heat of a hot-bed, a kitchen, or other room, and, on the approach of spring (probably at any period after the middle of January), a cellair, will afford a sufficiently high temperature; and the advantages of that of forcing a portion of surface in the natural state of growth of the plants would occupy twenty feet; and in the shady space of the vinery or peach-house, not applicable to other purposes, and without incurring any additional expense in fuel, or doing injury to the rest of abundant plants may be raised."

4205. Taking the stalks. Remove a little earth, and bending down the leaf you would remove, slip it off from the crown, without breaking or using the knife. The stalks are fit to use when the leaf is half-expanded; but a larger produce is obtained by letting them remain till in full expansion, as is practised by the market-gardeners. The stalks are tied in bundles of a dozen and upwards, and thus exposed for sale.

4206. To save seed. Leave one or two of the strongest flower-stalks to perfect their seeds, which they will do in July and August.

4207. Of the peapon and gourd tribe there are six species in cultivation, natives of India and the East, all tender or half-hardy annually, but producing fruit in the open air in Britain in the warmest period of our summers.

4208. The pumpkin, peapon, or, more correctly, pumpon, is the C. Pepo, L. (Pastisson, Fr.); a native of the Levant, and introduced in 1570. This is the melon or million of our early horticulturists, the true melon being formerly distinguished, by the name of
POIMPION and GOURD.

musk-melon. Though commonly cultivated in gardens for curiosity, yet, in some of the country villages of England, the inhabitants grow it on dunghills, at the backs of their houses, and train the shoots to a great length over grass. When the fruit is ripe, they cut a hole in one side, and having taken out the seeds, fill the void space with sliced apples, adding a little sugar and spice, and then having baked the whole, eat it with butter. (Nell.) Pumpkin-pie, Abercrombie says, is very common. On the continent, the fruit is a good deal used in soups, and also stewed and fried in oil or butter.

4209. The water-melon is the C. citrullus (Rumph. Am. 5. t. 146. and our fig. 473.), Pastegue, Fr.; Wassermelone, Ger.; and Cocomero, Ital. It is a native of the south of Europe, and introduced in 1597. It is rather more tender than the C. Pepo. This plant forms both the food and the drink of the inhabitants of Egypt for several months in the year; and is much used in the south of Italy. It requires nearly the same treatment as the common melon, but a larger frame to admit its more extended shoots to spread themselves. The fruit is large, green externally, white-fleshed, reddish towards the centre, succulent, and refreshing, but not high-flavored. It is generally considered as the melon of the Jews, mentioned in various parts of the Bible.

4210. The squash is the C. Melopepo (Potiron, Fr.; Pföbin Kürbiss, Ger.; and Popone, Ital.); a native of the Levant, and introduced in 1597. It is cultivated like the pompion, and the fruit is used in pies, or gathered when of the size of a hen's egg, dressed in salt and water, and sliced and served on a toast. It is also used for pickling. In North America it is cultivated as an article of food.

4211. The warted gourd (C. verrucosa) is a native of the Levant, and introduced in 1658. Its nature and uses are the same as those of the squash, and like it, it is cultivated in North America as an article of food.

4212. The bottle gourd, or false calabash (C. lagenaria), (Rumph. Am. 5. t. 144.) is a native of India, and introduced in 1597. Its culture and uses are the same as those of the two last sorts.

4213. The orange-fruited gourd (C. aurantia) is a native of India, introduced in 1802, and rather more tender than the common pompion. It has been hitherto cultivated chiefly for curiosity, and when trained spirally round a pole, or against a wall, and loaded with its yellow fruit, it is very ornamental. The fruit may be used like those of the other sorts.

4214. The vegetable marrow (C. succado) (fig. 474.) was introduced within these few years from Persia, where it is called Cicader. "The fruit," Sabine observes (Hort. Trans. vol. ii. 255.), "is of a uniform pale-yellow, or light sulphur-color; when full grown, it is about nine inches in length, four inches in diameter, of an elliptic shape, the surface being rendered slightly uneven by irregular longitudinal ribs, the terminations of which uniting, form a projecting apex at the end of the fruit, which is very unusual in this tribe. It is useful for culinary purposes in every stage of its growth; when very young, it is good if fried with butter; when large or about half grown, it is excellent either plain, boiled, or stewed with rich sauce; for either of these purposes it should be cut in slices. The flesh has a peculiar tenderness and softness, from which circumstance it has, I suppose, received its name, much resembling the buttery quality of the Beurré pears, and this property remains with it till it is full grown, when it is used for pies. It is, however, in its intermediate state of growth that I conceive it likely to be most approved. Compared with all the other kinds which I had growing, its superiority was decided; there were one or two which, in cooking, might be considered nearly as good, but these are bad bearers, and more difficult to cultivate, so that I consider the vegetable marrow without a rival." The culture of this species is the same as that of the others.

4215. Culture applicable to all the species. They are propagated from seeds which are large, and require to be covered nearly an inch. "Sow in April in a hot-bed under a frame or hand-glass, to raise plants for transferring to the open garden at the end of May under a warm aspect; or for planting out in the middle of May on a trench of hot dung under a hand-glass or half-shelter: otherwise sow, at the beginning of May, under a hand-glass without bottom-heat, for transplanting into a favorable situation; or sow three weeks later (after the 20th) at once in the open garden, under a south wall, for the plants to remain.
smaller-fruited kinds do best trained to an upright pole or trellis. From time to time earth up the shanks of the plants. As the runners extend five feet or more, peg down at a joint, and they will take root. Water copiously whenever warm weather without showers makes the ground arid." (Abcrorumbe.)

4216. The angelica is a biennial, a native of England, being sometimes found in moist situations, and is also common in Lapland and Iceland. It was cultivated in Britain in 1568, and probably more early. It rises from three to five feet high, with very large pinnate leaves, the extreme leaflet three-lobed. The flowers are greenish, and produced in September; the roots long and thick, and they, as well as the whole plant, are powerfully aromatic. Though the plant is only a biennial, it may be made to continue several years, by cutting over the flower-stem before it ripens seed; in which case it immediately pushes out below.

4217. Use. It was formerly cultivated on account of its leaf-stalks, which were blanched and eaten as celery: now they are used only when candied; and the young and tender stalks are for this purpose collected in May. Sometimes also the seeds and leaves are used in medical preparations.

4218. Propagation and culture. It delights in moist situations, or the banks of running water; but will grow freely in any soil and exposure. The plants are raised from seed, and, for a bed four feet and a half by six feet, sown in drills a foot apart, to be transplanted, half an ounce of seed will be requisite. "Sow in August, or as soon as the seed is ripe, as the plants will come up earlier and stronger than from a sowing in the spring. When the plants are advanced from four to six inches high, transplant them into rows two feet apart. The roots will soon strike in the soil, and advance quite in strong growth. In the second year, their strong erect branchy stalks will be several feet high, producing large umbels of seed, ripening in autumn, which, as well as the leaves of the plant, are used in medicine. But, for candying, the young shoots of the shoot and stalks of the leaves are the useful parts: being cut, while green and tender, in May and June, they are made by confectioners into the sweetmeat called Angelica. In the second year, if seed is not wanted, cut the plants down in May, and the stool will send out side-shoots; by repeating this practice every year, the same plant may be long continued. Cuttings will also grow." (Abcrorumbe.)

4219. The anise is an annual plant, a native of Egypt, and introduced to this country, according to Turner, in 1551. The lower leaves are divided into three lobes, deeply cut on the edges; the stem is a foot and a half high, dividing into several slender branches; the umbels large and loose, on rather long peduncles; the flowers are small, of a yellowish-white, and appear from June to August.

4220. Use. It is cultivated in Malta and Spain for its seeds, which are annually imported as medicinal, and for distillation and expression. In this country, it is occasionally grown in the garden to be used as a garnish, and for seasoning, like fennel.

4221. Culture. The seeds require to be sown in April, in a warm border, in a dry light soil; or raised in pots on heat, and removed to a warm site in May, where it will blossom and ripen seeds in August in favorable seasons. It does not bear transplanting, but the plants, when too thick, are to be thinned out to three or four inches’ distance.

4222. The coriander is a hardy annual plant, originally introduced from the East, but now naturalised in Essex, and other places, where it has long been cultivated for druggists and confectioners. The plant rises about a foot high, with doubly pinnated leaves, and produces an umbel of white flowers in June. The whole plant is highly aromatic.

4223. Use. In private gardens, it is cultivated chiefly for the tender leaves, which are used in soups and salads. On a large scale, it is cultivated for the seed, which is used by confectioners, druggists, and distillers, in large quantities.

4224. Culture. The plant delights in a sandy loam. It is raised from seeds, which may be sown in February, when the weather is mild and dry, and the quantity requisite for a bed four feet wide by six in length, to be sown in rows, is half an ounce; and when sown in drills, they may be nine inches apart, and the seed buried half an inch. " Where a constant succession is required, small successive monthly sowings will be necessary in spring and summer, as the plants in those seasons soon run to seed. There should be also small sowings in August and September, to stand the winter under the defence of a frame. The plants are to remain where sown." (Abcrorumbe.)

4225. The caraway is a biennial plant, a native of England, being occasionally found in meadows and pastures. It rises a foot and a half high, with spreading branches; the leaves are decomposed; the leaflets in sixes; it produces umbels of white flowers in June.

4226. Use. The plant is cultivated chiefly for the seed, which is used in confectionary and in medicine. In spring, the under leaves are sometimes put in soups; and in former times the fusiform roots were eaten as parsnips, to which Parkinson gives them the preference. In Essex, large quantities of the seed are annually raised for distillation with spirituous liquors.
HYSSOP, CHAMOMILE, ELECAMPANE.

4227. Culture. It is raised from seed, of which a quarter of an ounce is sufficient for a seed-bed four feet by five. Sow annually, in autumn, soon after the seed is ripe; the seedlings will rise quickly, and should be transplanted at the foot of a distance each way. In default of sowing in autumn, sow in March or April, either in drills or broad-cast; but the plants so raised, will not in general flower till the following year. When the seed is ripe, the plant is generally pulled up in gathering, especially in field-culture.

Subsect. 7. Rue—Ruta graveolens, L. (Lam. Ill. 345. t. 1.) Decam. Monog. L. and Rutaceae, J. Rue, Fr.; Route, Ger.; and Ruta, Ital.

4228. The rue is a perennial evergreen under-shrub, a native of the south of Europe, but cultivated in this country since 1562, and probably long before. It is well known by its fetid smell.

4229. Use. The leaves, are sometimes gathered as a medicinal simple, and are also given to poultry having the croup. In former days, it was called the herb of grace, from the circumstance of small bunches of it having been used by the priests for the sprinkling of holy water among the people.

4230. Culture. It is easily propagated by seeds, cuttings, or slips of the young shoots in March, April, or May, planted in a shady border. The plant delights in a poor, dry, calcareous soil; in which it will continue for many years, and if cut down occasionally, always in full leaf and well furnished with young shoots. Letting it run to seed, weakens the plant and shortens its longevity.

4231. The hyssop is a hardy evergreen under-shrub, a native of the south of Europe, and introduced in 1548. The stems rise a foot and a half high; the leaves are lanceolate, short, and somewhat obuse; it produces blue flowers from June to September. The whole plant has a strong aromatic odor.

4232. Use. The leaves and young shoots are occasionally used as a pot-herb, and the leafy tops and flower-spikes are cut, dried, and preserved for medicinal purposes.

4233. The varieties are—

The white, blue, and red flowered; but the blue is the original color, and most commonly cultivated.

4234. Propagation and culture. “It is raised by seed, by slips, and cuttings of the branches, and by slips of the root and top together. It likes a dry or sandy soil. When it is propagated by seed, sow in March or April a small portion, either broad-cast and raked in, or in small drills, six inches apart. The plants may mostly be transplanted into final beds in June or July, nine inches apart, or some may be planted as an edging; or you may also sow some seed for an edging to remain where sown. Give the edgings occasionally trimming, in their established growth; cutting away also any decayed flower-spikes in autumn. When the plants are rooted, cut the plants off at the base, and rooted off from established plants in March, April, August, or September; cuttings from the stalks in April and May; also rootless slips of the young shoots in June or July. After May, shade for a time, or plant in a shady border. If for culinary purposes, the distance from plant to plant may be nine inches; in the physic-garden, eighteen inches or two feet. Water at planting, and twice or thrice a week in dry weather till rooted.” (Abercrombie.)

4235. The chamomile is a hardy perennial, which grows wild in various parts of England in gravelly pastures, and by road-sides. The leaves are cut into threads, and the stem prostrate. The flowers are white in the rays and yellow in the disk, and appear in August and September. The whole plant is bitter and highly aromatic.

4236. Use. It is cultivated on account of the flower, which is a safe bitter and stomachic, and much used under the name of chamomile-tea. The double-flowering variety, though more beautiful than the single-flowered, is less useful; the aromatic principle not residing in the floescles of the ray, the multiplication of which constitutes the double flower. The double sort, however, is most cultivated by growers for the market, on account of its greater bulk and weight.

4237. Varieties. These are the common single, and the double flowered.

4238. Soil and culture. This herb delights in a poor sandy soil. “Both kinds are propagated by parting the roots, or by slips of the rooted off-sets, or of the runners. Detach them with roots, in little tufted sets, in March, April, or May; and plant them from eight to twelve inches asunder, giving water; repeat plantings occasionally till they root; they will soon overspread the bed, and produce plenty of flowers the same year in July and August, and continue several years productive.

4239. Taking the crop. “The flowers should be gathered in their prime, in June or July, just when fully-bloomed. Let them be spread to dry in a shady place; then put them in paper bags, and house them for use.” (Abercrombie.)

4240. The elecampane, found in moist pastures in the south of England, and one of the largest herbaceous plants we have, rising from three to five feet high; the lower leaves embrace the stem, are ovate and wrinkled, a foot long and four or five inches broad in the middle. It produces large heads of yellow flowers in July and August. The root is thick, fusiform, and aromatic. It was formerly in great repute, and the plant was cultivated in village gardens throughout Europe. In private gardens it still keeps its place in the physic-herb corner.

4241. Use. In France and Germany, the root is candied, and used as a stomachic, for X x 3
strengthening the tone of the viscera in general. As a medicinal plant, it possesses the general virtues of alexipharmics.

4242. Culture. It is propagated by offsets in autumn, after the plant has done flowering; these, if planted in a deep soil, rather moist, or in a shady situation, will be fit for use the end of the second year. Roots of this age are said to be preferable to those of older plants.

4243. The licorice is a hardy perennial plant, a native of the south of Europe, and introduced into this country in 1562. The roots run very deep into the ground, and creep to a considerable distance, sending up strong herbaceous stalks, four or five feet high; the leaves are composite, and consist of four or five ovate leaflets terminated by an odd one; these and the stalks are clammy, and of a dark green. The flowers come out in axillary spikes, of a blue color, in July and August. Stowe informs us, that the planting and growing of licorish began about the first year of Queen Elizabeth.

4244. Use. It is cultivated on a large scale for the brewers and druggists, and used in gardens for the saccharine juice obtained from the root by decoction, and used as an emollient in colds, fevers, &c.

4245. Propagation and culture. "Licorice is propagated by cuttings of the roots. On account of the depth to which the root strikes, when the plant has room to flourish, the soil should have a good staple of mould thirty inches or three feet in depth. Taking the small horizontal roots of established plants, cut them into sections six inches long; having traced out rows a yard asunder, plant the sets along each row, at intervals of eighteen inches, covering them entirely with mould. For the first year, you may cultivate a light crop of lettuce or onions between the rows. During the summer, keep the plot clear from weeds; and when the subordinate crop comes off, hoe and dress the ground. At the close of autumn, or as a winter dressing, fork or dig between the rows, to stir and refresh the surface; and cut down the decayed stems."

4246. Taking the crop. "After three or four years' growth, the main roots will be of a mature size, and fit for consumption or the market. In the course of the following winter, begin to dig them up, opening a trench close to the first row, as deep as the roots, then, with the spade, turn out all the roots clean to the bottom; so proceed from trench to trench, and prepare the ground for some other crop." (Abercrombie.)

4247. The wormwood is a perennial plant, well known, and frequent in calcareous commons and by road-sides in England. It rises from two to four feet high, covered with minutely divided hoary leaves. The flowers appear in small pendulous hemispherical bunches in August. The whole plant is intensely bitter and acromatic.

4248. Use. The seeds are used as stomachics, and the herb was formerly much used as a vermifuge. The growth of this plant, Neill observes, 'should be encouraged in poultry walks, it being found beneficial to them. The distillers in Scotland sometimes employ it in place of hops, and for their use, small fields of it are occasionally sown.'

4249. Propagation and culture. By seed, cuttings, or dividing the root: the latter is the easiest mode, and the future treatment may be the same as for rue or hyssop. The sea-wormwood (A. maritima), the Roman (A. pontica), and the Tartarian (A. santonica) are propagated chiefly by cuttings, and may be treated like the common species.

4250. The blessed thistle is an annual plant, a native of Spain and the Levant, and introduced in 1548. The leaves are long, elliptical, rough, runcinate, and variously serrated. The calyx is woolly, and the flowers yellow, appearing from June to November.

4251. Use. An infusion of the leaves is sometimes used as a stomachic, and is said to procure the return of appetite, where the stomach was injured by irregularities. A strong infusion promotes perspiration, and increases all the secretions. It was formerly used in cases of cancer; but at present is considered of little medical value.

4252. Culture. The seed is to be sown in autumn, in any light earth, and in a warm situation. Thin and keep free from weeds, the plants will flower the following June and July, and if not gathered, will produce seeds in August and September. Gather the herb when in flower, and take great care in drying it and keeping it in a dry airy place, to prevent its rotting or getting mouldy, which it is very apt to do.

4253. The balm is a hardy perennial, with square stems, which rise two feet high or more, furnished with large ovate leaves, growing by pairs at each joint. It is a native of Switzerland, and the south of France; produces flowers of a purplish color from June to October, and was introduced to this country in 1573. There is a variety with hairy leaves.

4254. Use. It is now little used, unless for making a simple balm-tea, which affords a grateful dilute drink in fevers, and for forming a light and agreeable beverage under the name of balm-wine.
4255. Propagation. It is readily propagated by parting the roots, preserving two or three buds to each piece, or by slips, either in autumn or spring.

4256. Culture. Plant the slips or sets in any bed of common earth, by dibble or trowel, and from eight inches to a foot apart, giving water, if dry weather. Those of the spring planting will soon grow freely for use the same year; and afterwards will increase by the root into large bunches of several years' continuance, furnishing annual supplies from March to September.

4257. Dried balm. Gather when coming into flower, and when the leaves are perfectly free from dew or moisture; then dry rapidly in the shade, or better in an oven; and when cool press the herbage into packages, and wrap them up in white paper till wanted for use. Keep the packages dry and in a close drawer.

Sect. XI. Plants used as Preserves and Pickles.

4258. Of plants used as culinary preserves and pickles, some are tender annuals, requiring to be reared to a certain stage of growth in hot-beds or stoves, as the capsicum and love-apple; others are marine plants, as the sambhires, more generally gathered wild than cultivated in the garden. The remainder are chiefly common garden-plants, used also for other purposes, as the red cabbage, Indian cress, &c. The whole occupy but a few square yards of the largest kitchen-garden; and, excepting the red cabbage, few of them are seen in that of the cottager for the purposes of this section.

4259. The love-apple is a tender annual, a native of South America, and introduced in 1596. The stem, if supported will rise to the height of six or eight feet; the leaves are pinnate, and have a rank disagreeable smell when handled; the flowers are yellow, appearing in bunches in July and August, and followed by the fruit in August and September. The fruit is smooth, compressed at both ends, and furrowed over the sides; it varies in size, but seldom exceeds that of an ordinary golden pipkin.

4260. Use. When ripe, the fruit, which has an acid flavor, is put into soups and sauces, and the juice is preserved for winter use like ketchup; it is also used in confectionary, as a preserve; and when green, as a pickle. Though a good deal used in England in soups, and as a principal ingredient in a well known sauce for mutton; yet, our estimation and uses of the fruit are nothing to those of the French and Italians, and especially the latter. Near Rome and Naples, whole fields are covered with it, and scarcely a dinner is served up in which it does not in some way or other form a part.

4261. Varieties. Those in general cultivation are —

| The large, small, cherry, and pear-shaped red | The large, and small, or cherry-shaped yellow |

4262. Estimate of sorts. "The first sort is in most estimation for domestic purposes, and should be cultivated accordingly; while a few plants of the other kinds may be raised for variety of the fruit."

4263. Propagation and culture. The plants must be raised and forwarded in a hot-bed, under glass, from about the vernal equinox till May. Sow in any general hot-bed about the end of March, or beginning of April, and as to quantity of seed, one ounce will produce sixty plants. As soon as the plants are about two inches high, if they are immediately pricked into another hot-bed, or into that where raised, singly into small pots placed in the hot-bed, they will grow more stocky, and can be more successfully transplanted. About the middle or end of May, transplant them, each with a ball of earth, into a south border, to have the full sun, that the fruit may ripen in perfection. Some may be planted close to a south wall, if vacant spaces can be had; but as they draw the ground exceedingly, do not set them near choice fruit-trees. Give water. During the first week or fortnight, if the nights be cold, defend them with hand-glasses, or by whitening a large garden-jot over each plant; or transplant upon holes of hot dung, earthed to six inches depth, and cover with hand-glasses. When they begin to run, train them to stakes, or, when planted near a wall or pale, nail up the branches.

4264. Wilted plants at the foot of a bed sloping steeply to the south, and trains the runners on it by pegging them down. They frequently strike root at the joints; he "tops" them as soon as their branches meet, clears off all the lateral shoots, and thins the leaves by which the fruit is exposed and well ripened. In the fine season of 1815, each plant so treated produced, on an average, twenty pounds' weight of fruit. (Hort. Trans. 346.) The fruit begins to ripen in August; gathered in October, and hung up in bunches in any dry apartment, it will continue good for use in November.

4265. To save seed. "Gather some of the best ripe fruit in autumn; clear out the seed; wash and cleanse it from the pulp, and dry it thoroughly; then put it up in papers or bags, for use next spring." (Abercornacle.)

4266. The egg-plant is a tender or green-house annual, a native of Africa, introduced in 1597. The plant rises about two feet high, with reclining branches; the flowers appear in June and July, of a pale-violet color, followed by a very large berry, generally of an oval shape, and white color, much resembling a hen's egg; and in large specimens, that of a swan.

4267. Use. In French and Italian cookery, it is used in stews and soups, and for the general purposes of the love-apple.
4268. **The varieties are**—

- The oval-shaped white  
- The globular-shaped white  
- The purple, or violet-colored, of both forms.

4269. **Culture.** The plants are raised from seed, which may be sown in March or April, in a hot-bed, in light rich earth. After they have shown two or three proper leaves, they may either be pricked out in another hot-bed, or planted in small pots, to be shifted in rotation, till in size No. 16, in which they will produce their fruit. If the plants, instead of being shifted into fruiting-pots, are planted against a wall or in a warm border in June, they will fruit in the open air, if the season is not unusually wet and cold.

4270. **To save seed.** Gather one or two ripe berries of each sort, large and well formed, and preserve them entire, till the seed is wanted for sowing.

**SUBSECT. 3. Capsicum. —** *Capsicum, L. Pent. Monog. L. and Solanaceæ, B. P.*

4271. **Of the capsicum there are three species in cultivation.**

4272. **The annual capsicum, or Guinea-pepper, is the C. annuum, L. (Knorr. Thess. 2. t. C. 6.),** an annual plant, which, though a native of India, endures the open air in this country during summer. It was introduced in 1548, and was cultivated in Gerard’s time. It rises about two feet high, producing long, linear, dark-green leaves, on a branchy stem. The flowers are white, and appear in June and July, succeeded by berries, varying in shape and color, and either long-podded, red and yellow; short-podded, red and yellow; round short-podded, red and yellow; or heart-shaped, red and yellow.

4273. **The cherry-pepper (C. cerasiforme), (Hort. Kern.),** is an annual plant, a native of the West Indies, which also stands our summer. It was introduced in 1759, has the same general character of foliage as the Guinea pepper, and flowers from June to September. It is characterised by its small cherry-shaped fruit, which is sometimes heart-shaped, bell-shaped, or angular, and in color red or yellow.

4274. **The bell-pepper (C. grossum), (Best. Eyst. Aut. 1. t. 11. f. 1.),** is a stowe biennial, a native of India, and introduced in 1759. It is of humble growth, flowers in July, and produces large red or yellow berries. It will endure the open air in summer, but requires a place in the stove during the winter and spring months.

4275. **Use.** The green pods, or inflated berries, of all these varieties, are used for pickling. They are sometimes also used in their ripe state, when they form a spice of the hottest quality, known by the name of Cayenne pepper. The berries of the last named species are deemed better for pickling than the others, the skin being thick, pulpy, and tender.

4276. **Culture.** All the three species, with their varieties, are raised from seed; a small parcel, or the produce of two pods, will be a sufficient quantity of each or of any one variety for ordinary supply. Sow all the annual sorts at the end of March, 14 or beginning or middle of April, in a moderate hot-bed, under a frame. Cover the seed a quarter of an inch deep. When the plants are two or three inches in growth, prick some into a newer slender hot-bed, to forward them for final transplanting; or in default of this, prick them into a bed of natural earth, at the beginning of May, if fine, settled, warm weather; defend them with a frame, or awning of mats, at night and in cold vicissitudes. Give water lightly at planting, and occasionally afterwards in moderate supplies, to assist their fresh rooting and subsequent growth. At the beginning of June, when the weather is settled warm, transplant them into the open garden, in beds of light rich earth, from twelve to eighteen inches apart, giving water. They will thus advance freely, flower in July or August, and produce plenty of pods from August till the end of September. Under the deficiency of a hot-bed or stove, or for succession, annual capsicums may be raised in a bed of light rich earth, under a hand-glass; but the sowing must be deferred to fine warm weather in May. Give the plants plenty of water, and cover them close at night, till danger from frost is over. At the close of June, transplant as above. The perennial species must be wintered in the stove.” (Abercrombie.)

4277. **To save seed.** Leave one or two of the largest and handsomest shaped pods to ripen in autumn; after gathering them, the best way is to hang them up in a dry place, and not take out the seed till wanted for sowing in spring.

**SUBSECT. 4. Samphaire, three Species of different Orders and Genera.**

4278. **Common samphaire is the Crithium Maritimum, L. (Eng. Bot. 819.); Pent. Dig. L. and Umbellifera, J. Perce-pierre, or Saint Pierre, Fr.; Meerfenchel, Ger.; and Finchio marino, Ital. (fig. 475. a)** It is a perennial plant, a native of Britain, and found on rocky cliffs by the sea, and in dry stone walls. The root-leaves are trinerved, those of the stem lanceolate and fleshy; the flowers appear on a stem of about eighteen inches high in August, and are of a yellow color. The name samphaire is a corruption of sampier, and this again a corruption of the French name Saint Pierre.

4279. **Use.** Samphaire forms an excellent pickle, and a frequent addition to salads. In taste, it is crisp and aromatic, and constitutes a light and wholesome condiment. It is generally gathered in places where it is found native; and the allusion to the practice by Shakspeare, in his description of Dover cliff, is well known. The plant is also used medicinally.
Edible Wild Plants.

4280. *Culture.* It is propagated by parting the roots, or by sowing the seed in April; but is rather difficult of cultivation. Marshal says, "it likes a cool situation; but yet prefers a sandy or a gravelly soil, and plenty of water. Some," he adds, "have found it to do best in pots, set for the morning sun only." Braddock placed it in a sheltered dry situation, screened from the morning sun; protected it by litter during winter, and in spring sprinkled the soil with a little powdered barilla: "This I do," he says, "to furnish the plants with that spirit of some warmth, it possesses of decomposing sea-water, from which it takes the fossil alkali, and rejects the muriatic acid. With this treatment it has continued to flourish at Thames Ditton for some years, producing an ample supply of shoots, which are cut twice in the season." (Hort. Trans. ii. 352.)

4281. *Golden samphire* is the *Inula Crithmifolia*, L. (Eng. Bot. 68.) Syn. Polyg. Super. L. and Caryophyllea. J. L'Inule perce-pierre, Fr.; Goldene Meerfenchel, Ger. (*fig. 475. b*) It is a perennial plant, found on sea-shores, generally within salt-water mark. It is occasionally gathered and brought to Covent Garden market, under the name of golden samphire; but has not, we believe, been introduced in the garden. It is used for the same purposes as the common samphire.

4282. *Marsh-samphire* is the *Salicornia Herbacea*, L. (Eng. Bot. t. 415.) Dian. Monog. L. and Chenopod. B. P. Salicorne, Fr.; Glasschmalz, Ger.; and Erbacel, Ital. (*fig. 475. c.*) It is an annual plant, a native of Britain, and not uncommon in salt-marshes, and other ais and islets of low land overflown by the sea. It is occasionally gathered and brought to market; and is used for pickling, and in salads, like the two plants above described. And the former species might be cultivated in the garden, by imitating a small portion of salt-marsh.

**Sect. XII. Edible Wild Plants, neglected, or not in Cultivation.**

4283. *The subject of edible wild plants* is introduced as highly deserving the study of the horticulturist; partly to increase his resources, partly to induce such as have leisure to try how far these plants may be susceptible of improvement by cultivation; but principally to enable the gentleman's gardener to point out resources to the poor in his neighborhood, in seasons of scarcity. All vegetables not absolutely poisonous may be rendered edible by proper preparation. Many sorts, for example, are disagreeable from their acrid and bitter taste; but this might be, in a great degree, removed by maceration, either in cold or hot water. The vegetable matter once reduced to a state of insipidity, it is easy to give it taste and flavor, by adding salt of some sort, which is an article never scarce through the influence of bad seasons; or by vinegar, or oils, or fats; by the addition of other vegetables of agreeable tastes and flavors, as of thyme, mint, celer- seed, onions, &c.; or by the addition of torrefied vegetable matter; as of the powder of roasted carrot, parsnip, potato, or dandelion-roots, or of beans, peas, or wheat; or, if it can be had, of toasted bread, which will render almost any thing palatable, and prolong the pleasure of eating many of the best things.

4284. *Gooseberry, birch, beech, willow, and other leaves,* we are told, were formerly eaten as salads; and there can be little doubt that aboriginal man would eat any green thing that came in his way, till he began to improve. It may be worth while for man in his present multiplied and highly civilised state, to reflect on these things, with a view to resources in times of famine, or in travelling or voyaging, or touching at or settling in new or uncultivated countries. (Parry's Voyage to the Polar Regions, 4to. 1821.) Edible wild plants may be classed as greens and pot-herbs, roots, legumes, salads, teas, and plants applied to miscellaneous domestic purposes.

**Subsect. I. Greens and Pot-herbs from Wild Plants.**

4285. *Black bryony.* Tamus communis, L. (Eng. Bot. 91.) Diec. Hex. L. and Smilacaceae, J. A twining perennial, growing in hedges, and commonly considered a poisonous plant; but the young leaves and tops are boiled and eaten by the country people in spring.

4287. *Chardock.* Sinapis arvensis, L. (Eng. Bot. 1741.) Tetrad. Siliq. L. and Cruciferae, J. A common annual weed in corn-fields. The young plant is eaten in the spring as turn-up tops, and is considered not inferior to that vegetable. The seeds of this have sometimes been sold for feeding birds instead of rape; but being hot in its nature, it often renders them diseased.

4289. *Shepherd's purse.* Thielepis bursa pastoris, L. (Eng. Bot. 1483.) Tetrad. Siliq. L. and Cruciferae, J. An excellent plant in Philadelphia, brought to market in large quantities in the early season. The taste, while it is raw, is somewhat bitter; but is softer and milder. This plant varies wonderfully in size and succulence of leaves, according to the nature and state of the soil where it grows. Those from the gardens and highly cultivated spots near Philadelphia, come to a size and succulence of leaf scarcely to be believed without seeing them. They may be easily bleached by the common method, and certainly, in that state, would be a valuable addition to the list of delicate culinary vegetables. (Correa de Sierra, in Hort. Trans. vol. iv. 445.)

4290. *Fat hen.* Chenopodium urbicum, (Eng. Bot. 717.) and C. album, (Eng. Bot. 1723.) Pent. Dig. L. and Chenopod. J. Both these plants are annuals, common among rubbish of buildings, dunghills, &c. Boiled, and eaten as spinage, they are by no means inferior to that vegetable. Several other native, but less common species of this genus, may be applied to the same use.
sub. 1. roots of wild plants edible.

4300. Arrowhead. Sagittaria sagittifolia, (L. (Eng. Bot. 84.) Polyan. Polyp. and Alismaceae, B. P. The roots of this aquatic perennial are said to be very similar to those of the West India arrow-root (Maranta Arundinacea, L.). They are sometimes dried and pounded, but are reported to have an acid unpleasant taste; though this might, it is believed, be got rid of by washing the powder in water.

4301. Common arrow. Arum maculatum, L. (Eng. Bot. 1293.) Polyan. Polyen. L. and Aridace, B. P. This plant is very common in hedges and woods in loamy soils; in the isle of Portland it is very abundant, and there the roots are dug out by the country people, macerated, steeped, and the powder so obtained is dried, and sent to London, and sold under the name of Portland sage.

4302. Mouse-hemp or mouse parsley. Orobus tuberosus, L. Com. Diand. Decan. L. and Leguminosee, J. The tubers are said to be chewed by the Scottish Highlanders as a substitute for tobacco. boiled till a fork will pass through them, and dried slightly and roasted, they are served up in Holland and Flanders in the manner of chestnuts, which they resemble in taste. (Dickson (Hort. Trans. ii. 538.) recommends planting them in a hill or border in a 6.
SUBSECT. 3. Leguminous Wild Plants Edible.
4309. Sea-peas. *Pisium maritimum*, L. (Eng. Bot. 1046.) Diad. Decan. L. and *Leguminosae*, J. (fig. 476.) These peas have a bitterish disagreeable taste, and are therefore rejected when more pleasant food is to be got. In the year 1555, however, when there was a great famine in England, the seeds of this plant were used as food, by which, according to Turner, thousands of families were preserved. The bitter of these seeds might in all probability be removed by steeping and kiln-drying, as in preparing for the mill peas which are to be split.

4310. Wild vetches. *Lathyrus*, *Vicia*, and *Ervum*, Diad. Decan. L. and *Leguminosae*, J. The seeds of all the British species of these genera may be used as peas. They are found in hedges, woods, and corn-fields, and are most prolific in dry seasons.

SUBSECT. 4. Salads from Wild Plants.

4312. Stone-crop, or orpine. *Sedum Telephium*, L. (Eng. Bot. 1312.) Decan. Penag. L. and *Sempervineae*, J. *Tipique Madam*, Fr. The leaves are eaten in salads like those of purslane, to which, by the French, it is considered equal.

4313. Sea-houndweed. *Convolvulus Soldanella*, L. (Eng. Bot. 314.) Pent. Monog. L. and *Convolvulaceae*, B. P. This plant abounds on sea-coasts, where the inhabitants gather the tender stalks, and pickle them. It is considered to have rather a cathartic quality.

4314. Sweet Cicely. *Scandia odorata*, L. (Eng. Bot. 677.) Penan. Dig. L. and *Umbelliferae*, J. The leaves of this plant used to be employed like those of chervil. The green seeds grow small, and used with lettuce or other cold salads, give them a warm agreeable taste. The smell of the plant attracts bees, and the insides of empty hives are often rubbed with it before placing them over newly-cast swarms to induce them to enter.

4315. Buckshorn-plantain, or star of the earth. *Plantago coronopus*, L. (Eng. Bot. 892.) Tetrand. Monog. L. *Plantagineae*, B. P. *Corne de Cerc*, Fr.; *Krahenfuss*, Ger.; and *Coronopo*, Ital. This is a hardy annual, native of Britain, found in sandy soils. It is a low spreading plant, with linear pinnated leaves, and round stalk; producing short spikes of starry flowers from May to August. It was formerly cultivated as a salad herb, and used like the common corn; but is now neglected in English gardens, perhaps on account of its rank and disagreeable smell. It is still, however, regularly sown in French gardens. It is raised by seed, which may be sown the first week in March; and after the plants have come up, they should be thinned so as each may occupy from five to nine square inches. To ensure a succession of tender leaves, cut off the flowers as they appear.

4316. Ox-eye daisy. *Chrysanthemum leucanthemum*, L. (Eng. Bot. 601.) *Syng. Polyg*. Super. L. and *Compositae*, J. *Marguerite grandiose*, Fr.; *Grasse Wucherhume*, Ger.; and *Leucantemo*, Ital. This is a perennial plant, common in dry pastures. The leaves, which spring immediately from the root, are obovate with foot-stalks; from these a stem arises from two to three feet high, furnished with oblong, embracing pinnatifid leaves. The flowers are large, with yellow disks and white rays, and appear in June and July. The young leaves were much used in Italy in salads in Staulin's time; and they are mentioned by Dr. Withering as being fit for this purpose. The plant is easily propagated by dividing the roots after the flowering season. To produce succulent tender leaves, it should be placed in soft, rich, moist earth.

SUBSECT. 5. Substitutes for Chinese Tea from Wild Plants.
4317. Speedwell. *Veronica spicata*, L. (Eng. Bot. 2.) Diad. Monog. L. and *Scrophulariaceae*, B. P. This plant is sometimes used as a substitute for tea; and is said to possess a somewhat astringent taste like green tea (*Camellia viridis*).

4318. Spring grass. *Anthoxanthus odoratum*, L. (Eng. Bot. 647.) *Diad. Dig. L.* and *Gramineae*, B. P. (fig. 477.) This is a highly odoriferous grass, a decoction of which is said to bear a considerable resemblance to tea.

4319. Other substitutes. The leaves of the black currant afford a very good substitute for green tea; and those of *Satefra graffifolia* are said, by Took (Russ. Emp.), to be used as tea in Siberia. *Betonica officinalis* (Eng. Bot. 1142) is said to have the taste and all the good qualities of foreign tea without the bad ones.

SUBSECT. 6. Wild Plants applied to various Domestic Purposes.
4320. Butterwort. *Pinguicula vulgaris*, L. (Eng. Bot. 70.) Diad. Monog. L. and *Lentibularaceae*, B. P. The inhabitants of Lapland and the north of Sweden give to milk the consistency of cream by pouring it warm from the cow upon the leaves of this plant, and then instantly straining it, and laying it aside for two or three days till it
acquires a degree of acidity. This milk are extremely fond of; and once made, they need not repeat the use of the leaves as above, for a spoonful or less of it will coagulate another quantity of warm milk, and make it like the first, and so on, as often as they please to renew their food. (Lightfoot's \textit{Flor. Scot.} p. 77.)

4321. \textit{Cow-parsnip.} \textit{Heracleum Spondylium. L. (Eng. Bot. 929.) Pent. Dig. L. and Umbelliferæ. J.} The inhabitants of Kamschatka, about the beginning of July, collect the foot-stalks of the radical leaves of this plant, and, after peeling off the rind, dry them separately in the sun; and then tying them in bundles, lay them up carefully in the shade. In a short time afterwards these dried stalks are covered over with a yellow saccharine efflorescence, tasting like licorice, and in this state they are eaten as a delicacy. The Indians have been wont to distill them with other herbs, thus prepared, contriv to get a very saccharine spirit from them, by first fermenting them in water with a greater or less quantity of sugar (\textit{Vaccinium uliginosum}), and then distilling the liquor to what degree of strength they please; which Guinelin says, be much more agreeable to the taste than spirits made from corn. (Lightfoot's \textit{Flor. Scot.})

4322. \textit{Kidney-vetch.} \textit{Vicia narbonensis L. (Eng. Bot. 1015.) J.} Formerly the young tops are said to have been used alone to brew a kind of ale; and even now, the inhabitants of Isla and Junta continue to brew a very potable liquor, by mixing two thirds of the tops of the heath with one of malt. (Lightfoot's \textit{Flor. Scot.})

4323. \textit{False or Wild Vetches, or Vetchlings.} The flower-buds of the marsh-marigold (Calla palustris, L.) form a safe substitute for capers; and likewise the young seed-pods of the common radish; and the unripe seeds of the nasturtium, or Indian cress. A species of spurge, common in gardens, (Euphorbia Lathyris,) is vulgarly called purslane, and for its fruiting it is said to be both hardy and poisonous, like the other plants of this genus, its seeds are sometimes substituted by the Pariscian restaurateurs for the pods of the true capers. For more minute details respecting the plants enumerated in this section, and various others which might be used as food, or in domestic economy, see Bryant's \textit{Flora Dietaetica}, and Lightfoot's \textit{Flora Scotica}, Hudson's \textit{Flora Anglica}, and the local florals of all parts of Europe.

\textbf{Subsect. 7. Poisonous native Plants to be avoided in searching for edible Wild Plants.}

4324. The principal poisonous plants, natives or growing in Britain, are the following: those marked thus (* *) are also the most valuable plants in the native \textit{materia medica}, the whole, for obvious reasons, ought to be known at sight by every gardener:—

\begin{itemize}
  \item Bitter Poisons, for which decoys, astrin- 
  \item gentes, and bitters are used in medicine. \textit{Chelidonium majus}, Cinna violescens L., and the natural species stated, are known as \textit{Nardostachys}, and \textit{Prunus Laurocerasus}.
  \item Aconitum, which should be counter- 
  \item powered by astrinents, as both, and 
  \item after the stomach restorative, by soft mucilaginous matters, as milk, 
\end{itemize}

fat broth, &c. \textit{Aconitum Napellus}, and \textit{Acantholoma acris}, of the \textit{Erica} genus, are \textit{Toxicodendron}.

\begin{itemize}
  \item Semen Poisons, to be counteracted

\textbf{4325. The poisonous fungi will be found in a succeeding section.}

\textbf{Sect. XIII. Foreign hardy herbaceous culinary Vegetables, little used as such in Britain.}

4396. The culinary plants of these countries are in general the same as our own; but a few may be mentioned which are more commonly cultivated in France, Germany, and America, than in England, but which would thrive in the latter country.

4357. The \textit{Claytonia perfoliata} (Pentan. Mono. L. and Portuicase, J.) is a hardy annual, a native of the New World, and a possible substitute for some wild sow thistles, which are not cultivated in this country. It will flower in April and May. Its perfoliate foliage is not very abundant, but it is exceedingly succulent, and not inferior to common spinach in flavor. It has no pretensions to supersede, or even to be generally cultivated as a spinach plant; but in very poor soils, under trees, or in other peculiar circumstances, it may be found a useful culinary vegetable.

4398. The \textit{Basella alba} and \textit{rubra} (Pentan. Trig. L. and Chenopodeae, J.) are stowe-biennials, raised on hot-beds near Paris, and transplanted into warm borders, where they furnish a summer spinach equal to that of the orache. (\textit{Hort. Tour}, 485.) They are also grown for the same purpose in China. (\textit{Living- 

done}, in \textit{Hort. Trans.} v. 24.)

4399. The \textit{Virginia poke} (Phytolacca decandra, Decan. Pentag. L. and Chenopodeae, J.) is a hardy perennial, with large rootous roots, shoots half an inch in diameter, and five or six feet high; the leaves five inches broad, smooth, and of a dark green. It grows vigorously in a good deep soil, and furnishes ample supplies of young shoots, which in America and the West Indies are boiled and eaten as spinach. (\textit{Miller's Diet. art. Phytolacca ; Correia de Serra, in Hort. Trans. iv. 446.)

4340. The \textit{White cabbage of China} (Brassica, sp. ?) used both as a herb and a salad (\textit{Babor \textit{or \textit{barbère}}, and \textit{wild cabbage of America} (B. bushelana, Muhl.), used as a pot-herb, might be grown for similar purposes in this country. The \textit{procumbent cabbage of China} is mentioned by Livingstone (\textit{Hort. \textit{Trans.} v. 55.), as being a hardy plant, supplying leaves the whole of winter.

4391. The \textit{rain water spinach} (Sideritis, J. and \textit{Boraginaceae, J.) is a hardy perennial, very prolific in lobed lucid green leaves which hold water (whence the name), and are used by the Indians both raw and boiled.

4382. The \textit{Aptos tuberosus}, Y. (Brazil. Decan. L. and Leguminaceae, J.) is a hardy tuberous-rooted perennial, a native of North America, the tubers of which are used by the Indians.

4383. The \textit{bread-root} (Pisorula esculenta, L. Diádel. Decan. L. and Leguminaceae, J.) is a hardy perennial, a native of Missouri, and used here as potatoes in this country.

4384. The \textit{Quassia} (Cassia esculenta, L. Hexan. Mono. L. and Sipholaceae, J.) is a native of North America, and there used as food.

4385. Other hardy vegetables. The \textit{Indian corn} (\textit{Zea mays}) is grown in some parts as a garden-plant, the ears being gathered green or partial ripe, and boiled, and boiled with molasses, or honey, is used as food. It is grown in the United States, and its seeds, to be used as a substitute for rice: the Polish millet (\textit{Digitaria sanguinalis}) is grown for this purpose in the cottage gardens in Poland; as is the carnation poppy (\textit{Papaver somniferus}), for its seeds, which form a seasoning to buck-wheat porridge. Nigelia sativa and \textit{Nigella sativa} of \textit{Papaveraceae} are cultivated in America, and are used as celery in this country, in soups and also in puddings. The \textit{Fukin mustard} (\textit{Sinapis Fokiniana}) is a hardy annual, and the most extensively used herbaceous plant in China, being, as Livingstone informs us (\textit{Hort. Trans.} v. 54.), carried about the streets of Canton and other towns in the boited state. The \textit{amaranth} is a hardy annual, grown in China as a spinach plant, and a number of others belonging to the \textit{Crucifère}, \textit{Chenopodeae}, \textit{Portulaceae,} &c. might be mentioned. (See Forsder's \textit{Plant. Escent. Austr.} \textit{Bryant's, Flora Dietaetica ; Le Bon Jardiner ; Modern Books of Travels, &c}.)
Sect. XIV. Edible Fungi.

4336. Only one species of edible fungi has yet been introduced to the garden, though there can be no doubt the whole would submit to, and probably be improved by, cultivation. All of them are natives of Britain, and may be gathered wild at certain seasons, so that though they do not enter into the plot of the cottager, they are, or may be, enjoyed by him. In Poland and Russia, there are above thirty edible sorts of fungi in common use among the peasantry. They are gathered in all the different stages of their growth, and used in various ways: raw, boiled, stewed, roasted; and being hung up and dried in their stoves or chimneys, form a part of their winter stock of provisions. Fungi, however, are not equally abundant in Britain, owing to the general cultivation of the soil; and therefore the good sorts being little familiar to the cottager, most of them are passed over as deleterious. Indeed the greatest caution is requisite in selecting any species of this tribe for food; and though we have given a catalogue both of the good and bad sorts of mushrooms, we can advise none but the botanist to search after any but the common sort (Agaricus campestris) as food.

4337. The mushroom is a well known native vegetable, springing up in open pastures in August and September. It is most readily distinguished, when of middle size, by its fine pink or flesh-colored gills, and pleasant smell; in a more advanced stage, the gills become of a chocolate color, and it is then more apt to be confounded with other kinds of dubious quality; but that species which most nearly resembles it, is slimy to the touch, and destitute of the fine odor, having rather a disagreeable smell: further, the noxious kind grows in woods or on the margins of woods, while the true mushroom springs up chiefly in open pastures, and should be gathered only in such places.

4338. Use. The garden-mushroom is eaten fresh, either stewed or boiled; and preserved as a pickle, or in powder, or dried whole. The sauce commonly called ketchup (supposed, by Martyn, from the Japanese, ki-jap,) is, or ought to be, made from its juice, with salt and spices. Wild mushrooms, from old pastures, are generally considered as more delicate in flavor, and more tender in flesh, than those raised in artificial beds. But the young, or button mushrooms, of the cultivated sort, are firmer and better for pickling; and in using cultivated mushrooms, there is evidently much less risk of deleterious kinds being employed. (Neill and Martyn.)

4339. Species. The following catalogue of edible and poisonous mushrooms is taken from Sowerby's splendid work on English fungi.

4340. General criteria of wholesome and deleterious fungi. Unwholesome fungi will sometimes spring up even on artificial beds in gardens; thus, when the spawn begins to run, a spurious brood are often found to precede a crop of genuine mushrooms. The baneful quality of the toad-stool (A. virius) is, in general, indicated by a sickly nauseous smell, though some hurtful sorts are so far without any thing disagreeable in the smell, as to make any criterion, drawn from that alone, very unsafe. The wholesome kinds, however, invariably emit a grateful rich scent.

4341. Antidote to poisonous sorts. All fungi should be used with great caution, for even the champignon and edible garden-mushrooms possess deleterious qualities when grown in certain places. All the edible species should be thoroughly masticated, before taken into the stomach, as this greatly lessens the effects of poisons. When accidents of this sort happen, vomiting should be immediately excited, and then the vegetable acids should be given, either vinegar, lemon-juice, or that of apples; after which, give ether and antispasmodic remedies, to stop the excessive bilious vomiting. Infusions of gallnut, oak-bark, and Peruvian bark are recommended as capable of neutralising the poisonous principle of mushrooms. It is, however, the safest way not to eat any of the good but less common sorts, until they have been soaked in vinegar. Spirit of wine and vinegar
extract some part of their poison; and tannin matter decomposes the greatest part of it. (Botanist's Companion, vol. ii. p. 145.)

4342. Culture. For the culture of the common mushroom, see Chap. VII. Sect. XIV. (4342.) With respect to the other edible sorts, as already observed, they are seldom gathered for use in Britain, excepting by experienced botanists; and none of them, as far as we know, have yet been brought under cultivation. We think that some of them, as the A. aurantiacus, A. deliciosus, and A. pratensis, might very readily, and without danger, be introduced to the garden; treating them like the garden-mushroom, or imitating the climate of the season of the year in which they are found in perfection, and the soil, situation, and exposure, &c., where they are found in greatest abundance, and of the best quality. In the first instance, it would, perhaps, be preferable to propagate from seed, in order to make sure of the species. In the present improved state of horticulture, if this branch of culture were once attempted, it would soon be rendered available by every gardener who can cultivate the common mushroom.

Subsect. 2. Morel. — Phallus esculentus, L.; Helvella esculenta of Sowerby (tab. 51.); and Morchella esculenta of Persoon. Cryptogamia Fungi, L. and Gymnocarpi, Persoon. In French, German, and Italian, not distinguished from the Champignon by any popular name. (fig. 479.)

4343. The morel is distinguished by its cylindrical, solid, or hollow stem, white and smooth; the cap is hollow within, and adhering to the stem by its base, and latticed on the surface with irregular sinuses. The height is about four inches. It rises in the spring months, in wet banks, in woods, and in moist pastures. It is in perfection in May and June, and should not be gathered when wet with dew, or soon after rain. Gathered dry, they will keep several months.

4344. Use. Morels are used, either fresh or dried, as an ingredient to heighten the flavor of gravies, ragouts, &c.

4345. Culture. Though this vegetable has not yet been introduced in garden-culture, like the mushroom, there can be no doubt of the attempt being attended with success. The spawn should be collected in June, and planted in beds or ridges, differently composed, and some laid up for use in dry and moist envelopements, in order, by experiment, to come to the best mode of cultivation. Lightfoot says, he has raised the phallus from seed.

Subsect. 3. Truffle, or Subterraneous Puff-ball. — Tuber Cibarium, Sowerby. (tab. 309.) Cryptogamia Fungi, L. and Angiocarpi, Per. Truffe, Fr.; Truffel, Ger.; and Tartufi, nero, Ital. (fig. 480.)

4346. The truffle is a subterraneous fungus, growing naturally some inches below the surface in different parts of Britain; and very common in the downs of Wiltshire, Hampshire, and Kent, where dogs are trained to scent it out. The dogs point out the spot by scraping and barking; and the truffles, which are generally found in clusters, are dug up with a spade. The truffle is globular, seldom the size of a hen's egg, without any root, and of a dark color, approaching to blackness. The surface is uneven and rough; the flesh firm, white while young, but when old, it becomes black, with whitish veins.

4347. Use. They are used, like the mushroom, in stuffings, gravies, and other high-seasoned culinary preparants. They are generally procured from Covent Garden market, as they bear carriage to any distance.

4348. Culture. "No attempt," Neill observes, "it is believed, has hitherto been made to cultivate truffles; but of the practicability of the thing there seems no reason to doubt. In their habits of growth, indeed, they differ essentially from the mushroom; but it is certainly possible to accommodate the soil and other circumstances to the peculiar nature of the fungus. It has been said, that the tubercles on the surface of truffles are analogous to the eyes or buds of potatoes, and that they have been propagated, like potatoes, by means of cuts furnished with tubercles; it may however be suspected, that the pieces thus planted contained ripe seeds. Truffles, we may add, seem to delight in a mixture of clay and sand; and a moderate degree of bottom heat, such as is afforded by a spent hot-bed, might probably forward their vegetation." (Ed. Encyc.)

4349. The edible British fuci may be shortly enumerated, because some of them are occasionally used as condiments by families living near the sea-coast; and because they furnish articles of resource for the local poor, especially in seasons of scarcity. There are numerous species; all of which, in common with every other class of sea-weeds and zoophytes, are employed in gardening as manures; and in general economy for making kelp or alkali. The following are the principal of the British species, which are considered edible by the inhabitants of sea-shores.
Fucus saccharinus. Sweet fucus, or sea-belt. (fig. 481. a) Lightfoot mentions, that the common people on the coast of England sometimes boil this species as a pot-herb. Anderson says, the Icelanders boil it in milk to the consistence of porridge, and eat it with a spoon. They are also said to soak it in fresh water, dry it in the sun, and then lay it up in wooden vessels; it soon becomes covered with a white efflorescence of salt, which has a sweetish taste, and in this state they eat it with butter. They also feed their cattle with this species.

F. palmatus. L. Dulse. (fig. 481. b) Both the tender stalks and young fronds are eaten recent from the sea, commonly without any preparation; they are sometimes considered as forming a salad, but more generally as a kelp. Dulse formerly was frequently dried, and brought to table. It is said, that the inhabitants of the Greek islands are fond of this species, adding it to ragouts and olos, to which it communicates a red color, and at the same time imparts some of its rich and gelatinous qualities. The dried leaves, infused in water, exhale an odor somewhat resembling that of sweet violets, and they communicate that flavor to vegetables with which they are mixed. Lightfoot mentions, that in the Isle of Skye, in Scotland, it is sometimes used in fevers, to promote perspiration, being boiled in water, with the addition of a little butter. It grows not uncommonly on rocks which are barely uncovered at the ebb of the tide; but is more frequent as a parasite on F. nodosus; and it occurs also on the stems of F. digitatus, attaining in this situation a considerable size, perhaps twelve or fifteen inches long, while, in general, it is only about six or eight inches. It is soft and limber, and does not become rigid by drying, being of a more loose texture than many other sea-weeds.

F. edulis. L. red dulse (fig. 481. c), is by many preferred to the F. palmatus, especially for roasting in the frying-pan. Like that species, its smell somewhat resembles sweet violets. It is of a deep, opaque, red color, giving out a purple dye.

F. esculentus. L. Harderlocks, or henware. (fig. 482. a) The mid-rib, stripped of its membrane, is the part chiefly eaten. In Orkney, the pinnae are also eaten, under the name of muckle.

F. ciliatus, L. ciliated dulse, and F. digitatus, fingered dulse, sea-girdle, and hangers (figs. 482. b), are sometimes gathered and eaten like F. edulis, palma-tus, and other species.

F. digitatus. In Scotland, the stem of this species is used for making handles to pruning-knives. A pretty thick stem is selected, and cut into pieces about four inches long. Into these, while fresh, the blades are stuck, and as the stem dries, it contracts and hardens, closely and firmly embracing the hilt of the blade; when these handles have become hard and shrivelled, and tied with metal, they are hardly to be distinguished from harts-horn.

F. pinnatifidus. L. Pepper dulse. In Scotland, it is eaten along with the F. palmatus, and in Iceland it is used instead of spice. This species is common to Scotland, Iceland, the Red Sea, and the shores of Egypt.

F. natans. L. Floating fucus. The succulent fronds, Turner mentions, are selected and picked like samphire; and the young shoots are eaten as a salad, seasoned with juice of lemons, pepper, and vinegar.

Ulva lactuca, L. (fig. 482. c) Lettuce-leaves, or oyster-green. The thin, green, pellucid membranes of which this vegetable is composed are eaten raw, as a salad, and esteemed a great delicacy by such as have been accustomed to the use of marine vegetables.

Supplies. No submarine production has hitherto been cultivated in the garden; though it might be worth while to try what could be done by a stone cistern of salt-water, and other contrivances. In the mean time, families in any part of Britain or Ireland, desirous of enjoying these vegetables, might have them regularly forwarded from the sea-shores, especially from such as are rocky. There are very few species known to be absolutely poisonous.

Edible nests. We may add, as matter of curiosity, that the transparent edible nests of the East Indies, containing much larger quantities of the leaves of the red and the East, are now generally believed to be almost entirely composed of gelatinous fucul; and more especially of the F. liche-woide. (Turner, t. 118.) The plant is also in high estimation for the table in India.

Horticultural Catalogue. — Hardy Fruit-trees, Shrubs, and Plants.

The hardy fruits of a country may be considered in reference to the vegetable appendages of the table, as next in utility to bread, corn, and culinary esculents. The excellent meats which they afford to the second course, and their contributions to the dessert, give them a peculiar value in the domestic economy of all those whose condition in life rises above the care of mere subsistence; and there are some sorts, as the gooseberry and apple, which, happily, either are or may be within the reach of the most humble occupier of a cottage and garden. Many fruits are as wholesome as they are pleasant; and some greatly assist the cure of particular diseases. Cider, perry, and
the various wines which may be made from the juice of fruits, are acceptable offerings to the social circle, when made in the best manner, and form important articles of commerce. We shall arrange the **Hardy Fruits** as —

4362. **Kernel-Fruits or Pomes**; including the apple, pear, quince, medlar, service.

4363. **Stone-Fruits**; as the peach, nectarine, almond, apricot, plum, and cherry.

4364. **Berries**; as the mulberry, barberry, elderberry, gooseberry, currant, raspberry, cranberry, and strawberry.

4365. **Nuts**; as the walnut, chestnut, filbert.

4366. **Native and neglected Hardy Fruits**, deserving cultivation, or useful in domestic economy, as the sloe, bird-cherry, wild service, mountain ash, bilberry, &c.

4367. **The varieties of most of these fruits** are so numerous, and each described as having so many good qualities, that the inexperienced selector may well be puzzled in making a choice, even from the comparatively limited lists which we have prepared for the following sections. When to all the names in these lists, and those of the nurserymen, we add the numerous new names annually brought forward by the Horticultural Societies of this country and of France, the difficulty of selection seems insuperably increased. The experienced and well informed gardener will be able to find out his way in this labyrinth; but what are others to do? We would say, as a prudent mode, consult the selections recommended by eminent practical men; as Abercrombie, M'Phail, Forsyth, Nicol, Macdonald, &c. which we have given in this chapter, and also in those on planting the kitchen-garden and orchard. (2498. and 2597.) There are probably not half so many distinct sorts, as there are names in use; and of that half, most likely two thirds are not worth cultivating. Of most of the sorts originated from seed, sufficient time has not elapsed to judge of their merits; they are all described as good; but unquestionably many of them are worth little in comparison with the best old sorts. Some of the new cherries and peaches might be added as examples; and the Poona grape, lately imported from the East Indies, and stated to be “a valuable addition to our gardens” (Hort. Trans. iv. 517.,) has been in the country (in the Brompton Nursery, for example), for an unknown length of time, under a different name. It is one of the worst descriptions of raisin grapes, with a small elliptical berry, having little flesh, juice, or flavor. — We make these remarks not to discourage from originating or importing new fruits; nor to dissuade from choosing new sorts; but to guard the inexperienced against being led away by names and appearances. The Horticultural Society are doing much to illustrate the subject of fruits, and in a few years they will no doubt settle a nomenclature, and determine the merits of all the fruits now in Europe, or perhaps the world.

**Sect. I. Kernel-Fruits.**

4368. **The principal hardy kernel-fruits** are the apple and pear, too well known for their important uses to require any eulogium. In this section are also included the quince, medlar, and service.

4369. **The apple** is a spreading tree with the branches more horizontal than in the pear-tree; the leaves ovate; the flowers in terminating umbels, produced from the wood of the former year; but more generally from very short shoots or spurs from wood of two years’ growth. The fruit is roundish, umbonate at the base, and of an acid flavor. In its wild state, it is termed the crab, and is then armed with thorns, with smaller leaves, flowers, and fruit, and the pulp of the latter extremely acid. It is a native of most countries of Europe in its wild state; and the improved varieties form an important branch of culture in Britain, France, Germany, and America, for the kitchen, the table, and for the manufacture of cider. From whence we at first received the cultivated apple is unknown; but in all probability it was introduced by the Romans, to whom twenty-two varieties were known in Pliny’s time (52.), and afterwards the stock of varieties greatly increased at the Norman conquest. According to Stow, carp and pepins were brought into England by Mascal, who wrote on fruit-trees in 1572. The apple-tree is supposed by some to attain a great age. Haller mentions some trees in Herefordshire that attained a thousand years, and were highly prolific; but Knight considers two hundred years as the ordinary duration of a healthy tree, grafted on a crab-stock, and planted in a strong tenacious soil. Speckley (Hints, 58.) mentions a tree in an orchard at Burton-joyce, near Nottingham, of about sixty years old, with branches extending from seven to nine yards round the bole, which, in 1752, produced upwards of 100 pecks of apples. Of all the different fruits which are produced in Britain, none can be brought to so high a degree of perfection, with so little trouble; and of no other are there so many excellent varieties in general cultivation, calculated for almost every soil, situation, and climate, which our island affords. Very good apples are grown in the Highlands and Orkneys, and even in the Shetland Isles, (Caled. Hort. Mem. vol. ii.) as well as in Devonshire and Cornwall; some sorts are ripe in the be-
ginning of July, and others, which ripen later, will keep till June. Unlike other fruits, those which ripen latest are the best.

4370. For pies, tarts, sauces, and the dessert, the use of the apple is familiar to every one. Duduit, of Maxces, has found that one-third of boiled apple-pulp, baked with two thirds of flour, having been held in the oven for two hours, makes a very white paste, of an extreme palatable and light. (New Month. Mag. June 1851.) The fermented juice forms cider, a substitute both for grape-wine and malt liquor. In confectionary, it is used for comfits, compotes, marmalades, jellies, pastes, tarts, &c. In medicine, verjuice, or the juice of crabs, is used for sprains, and as an astringent. By the French, in the manufacture of sugar, with the other sugars. It makes a very fine wine of which little inferior to Rhenish wine. Lightfoot affirms that the crab mixed with cultivated apples, or even alone, if thoroughly ripe, will make a sound, masculine wine. The apple, when ripe, is largely used for tarts, jellies, and other sweet dishes. It is also used in the form of Bosc pies, a familiar and delicious dish. Those who have this property when green, are particularly valuable for affording sauces to geeze early in the season, and for succoing the gooseberry in tarts. For cider, an apple must have a considerable degree of astringency, with or without the presence of sugar or richness. The best kind, Knight observes, are the stocky, dry, and fibrous; and the Siberian Harvey, which he recommends as one of the very best cider-apples, is unfit either for culinary purposes or the table. Knight has found that the specific gravity of the juice of any apple is a very important factor in the preservation of the strong spirit which is obtained from cider.

Considering the various uses of the apple, we agree with Speedy in regarding it as a fruit "of more use and benefit to the public in general, than all the other fruits, the produce of this island, united."

4372. Varieties. Tusser, in 1575, mentions in his list of fruits, "apples of all sorts." Parkinson, in 1629 (Flora Londinensis), says thirty years before, several kinds of apples were cultivated by the industrious and skilful gardener, Harris, through the plain industry of one Harris, a fruiterer to Henry VII, that the fields and environs of about thirty towns in Kent only, were planted with fruit from Flanders, to the universal benefit and general improvement of the trade. A. T. Brown and H. rug., in the Horticultural Transactions, by the Kew Alber, to the court of France, in the time of Charles I., collected in Normandy, 80 sorts of cider-apple trees, and when he returned to England, encouraged the planting them throughout the county of Hereford. Hartlib, in 1650, speaks of "one who had two hundred sorts of apples," and "very believes there are nearly as many sorts in England; and he, in 1668, selected from the information of the most skilful gardeners about London, a list of 78 sorts. Succeeding writers have been enabled greatly to increase the list, partly from the almost annual accession of sorts received from the continent during intervals of peace, but principally from the great numbers raised from seeds. A variety of apple, like those of most other plants, is increased by seedling; and hence arises the great variety. The enumeration of the several sorts, given by Parkinson, Evelyn, and other authors, many of them are not now to be found, or are so degenerated or diseased, as no longer to deserve the attention of the planter. "The molt," Knight observes, "and its successful rival, the red-streak, with the musts and golden-pippin, are in the last stage of decay, and the stire and foxwhelp are hastening rapidly after them." After making a great variety of experiments for several years, and after many attempts to propagate every old variety of the apple, this author observes (Tr. on Apple and Pear, 15), "I think I am justified in the conclusion, that all plants of their kind may be propagated by cuttings. In the same degree of the skill of the gardener, the sires may be improved and the progeny of grafts for propagation, and improve, in a certain degree, the hardiness and the age, and therefore the ripeness of the fruit. The schools, which have been some years in the practice of planting and grafting, and which have been employed in the propagation of the apple, for the last twenty years, have been attended on the progress of that life, in the habits of its youth, its maturity, and its decay; though they will not be any way affected by any accidental injuries the parent tree may sustain after they are detached from it."

4373. Knight next directed his attention to raising new varieties from seeds, and has, by crossing one sort with another, and by having constantly several thousand of seedlings rearing, from which, as they show fruit, to select the best sorts, succeeded in producing several new varieties of apples, much esteemed for their excellence. In 1656, he printed a short work on the improvement of the apple, which is still in great value, and the Horticultural Transactions, and a compend of their history and properties will be found in our table (next page). Several eminent horticulturists, in different districts, are now engaged in a similar manner; and there can be little doubt a valuable accession will, in a few years, be made to this class of fruits. Some, however, as Williamson (Hort. Trans. iii. 201), and Speedy (Hists. 188), consider that the deterioration of the apple and other fruits may be owing to the climate, and that the return of genial summers would restore to us from old trees as good fruit as heretofore. Such also is our opinion, and Knight's doctrine appears to contrary to general analogies in vegetable life. He is unquestionably true that all varieties have a tendency to degenerate into the primitive character of the species; but to us it appears equally true, that any variety may be perpetuated with all its excellencies by proper culture, and more especially varieties of trees. However unsuccessful Knight may have been in continuing the perseverance of the sorts he had, yet we cannot alter our conviction, that by grafting from these sorts they may be continued, such as they, were or were when the scions were taken from the trees, to the end of time. As to plants propagated by extension, "partaking in some degree of the same period of life as to parents," we cannot admit the idea as at all probable. Vines, olives, poplars, and willows have been propagated by extension for ages, and are still, as far as can be ascertained, as vigorous as they were in the time of Noah or Pliny.

4374. A numerous list of varieties may be considered as puzzling to inexperienced persons who have to select for a garden or an orchard. Sabine (Hort. Trans. iii. 353) justly observes, that the stock of apples requires reduction rather than increase; and adds, that one of the chief objects to which the attention of the Horticultural Society is at present directed, is to make a judicious selection.

4375. A great variety of apple-trees in a bearing state may be seen in different nurseries both in Britain and Ireland. The following is a list of those in the Horticultural Transactions, and the various nurseries, either young plants newly worked, or plants in a state of bearing, fixed on and marked, to be taken up at the proper season. The advantages of this mode, especially to such as possess but a small garden, are very considerable to require consideration.

4376. No well arranged catalogue of apples has yet been published, because, in general, only a limited number of sorts fall under the eye and experience of one individual. Such a work seems more likely to be accomplished by public bodies, and it is worthy of their attention. In the mean time, we present the best arrangement in our power of sorts readily procured from British nurseries, including most of the newly originated varieties, of which accounts have been published, and grafts distributed, among the commercial gardeners.
### DESSERT APPLES—PEARMAINS.
Common Character: Full at the footstalk, in general larger than Pippins.

</table>
DESSERT APPLES. — QUEENINGS. — A subvariety of Rennets.

DESSERT APPLES. — NON-PAREILLS. - A subvariety of Nonpareils. Above middle size; whitish-green, but slightly tinged with red.

DESSERT APPLES. — CALVILLES. - A subvariety of Calvilles. Conical ribbed; small-sized; light green, generally early apples, great bearers, and usually propagated by cuttings. Those marked (?) are good eating apples.

DESSERT APPLES. — COBLINGS. - A subvariety of Coblings; fruit small, twigs nodose.

DESSERT APPLES. — BURKNOTTS. - A subvariety of Burknotts; fruit small, twigs nodose.
### A DESCRIPTIVE CATALOGUE OF APPLES — DESSERT APPLES — continued.

**Notes:**
- The table lists various apple varieties, their descriptions, and characteristics.
- Each variety is categorized based on its origin and use, such as dessert, culinary, or ornamental.
- The table provides information on the ripening period, size, color, and other relevant details.\n- The character of the tree is described, including its fruit's general reputation and utility.

**Note:** The table above represents a portion of a descriptive catalogue of apples, focusing on various varieties of pippins, rennets, and coddlings, along with their characteristics and ripening times. Each entry includes details such as the year of origin, size, figure, color, and consistency, which are crucial for gardeners and fruit enthusiasts to choose the most suitable varieties for their climate and region. The catalogue also highlights the character of the tree, including its general reputation and any notable features like hardy nature, disease resistance, or good for culinary uses. The table is designed to help in making informed decisions about which apple varieties to plant and how they perform under different conditions. The variety names are meticulously documented, with some entries noting their origins and synonyms, providing a rich resource for further study and collection. The overall aim is to promote the cultivation of diverse apple types, ensuring a rich and varied fruit harvest.

**PRACTICE OF GARDENING.**

**PAR. III.**
PROPAGATION. The apple, like most other hardy trees, may be propagated by seeds, cuttings, suckers, layers, or grafting: by seeds, for obtaining new varieties, and by the other modes for continuing such as in estrem.

The first business here is, the choice of the seeds; which should be taken from fruits, having the properties it is desired to perpetuate or improve in the greatest degree. The seeds of apples proper for crossing or reciprocal impregnation, appear to be those which have a great many qualities in common, and some different qualities. Thus the golden pippin has been crossed by other pippins or rootstocks, to produce a large stock of seed which is capable of producing a new variety than the above mode; but will be almost equally certain of producing a variety destitute of valuable qualities; the qualities of parents of so opposite natures being, as it were, crudely jumbled together in the offspring.

838. In the mode of cutting out the stems of the stamens of the blossom to be impregnated, and afterwards, when the stigma is mature, introducing the pollen of the other parent, is unquestionably the most scientific mode of performing the operation. In this way he produced those excellent apples, the Downton, red and yellow, and the Newton, the one parent of the same pollens as the Golden pippin, and the other of the pollen of the golden pippin. The Bridgwood pippin he produced from golden pippin blossoms (divested of their stamens) dusted with the pollen of the golden harvey apple. The seeds may be sown in autumn, in light earth, covered an inch, and either in pots or beds. The end of the 1st year, they should be looked after, to see they are not stranded; and the young shoots should be thinned. Afterwards they should be removed to where they are to produce fruit; and for this purpose the greater the distance between the better. It should not be less than six or eight feet every way. The quickest way to bring them into bearing.

839. Macdonald, an eminent Scotch horticulturist, has also succeeded in obtaining fruit from seedlings raised by this mode of propagation. He states (1814) as the use of this mode of propagation. In 1808, he selected some blossoms of the nonpareil, which he impregnated with the pollen of the golden pippin and of the Newton pippin. When the apples were fully ripe, he selected some of the best, from which he obtained seed. When the seedlings were raised, he selected a seedling, which he transplanted into a frame, in which he sowed, in 1811, the seeds, which he transplanted into the open ground, in spring 1809. In 1811, he picked out a few of the strongest plants, and put them singly into pots. In spring 1812, he observed one of the plants showing fruit-buds. He took a few of the twigs, and grafted them on a healthy stock on a wall; and in 1813 he had few apples. This year (1816) his seedlings yielded several dozen, and also his grafts; and he mentions, that the apples from the grafts are the largest. He is of opinion that in giving names to seedlings, raised in Scotland, the word "Scotch" should be mentioned.

4384. By cuttings. Every variety of apple may be grown from cuttings; though with much greater facility than others. All those of the burknot and codling tribes grow as well this way as by any other, and some alledge, that the trees so raised are not liable to canker (Hort. Trans. vol. i. p. 120.), which is supposed to be owing to their putting out no tap-root, but spreading their numerous fibres from the knot or burr horizontally. Even the golden pippin may be continued in this way, and the trees have remained seven years in perfect health, when grafts taken not only from the same tree, but from the very branch, part of which was divided into seedlings, cankered in two or three years. "All apple-trees raised in this way," Biggs observes, "from healthy one-year-old branches, with blossom-buds upon them, will continue to go on bearing the finest fruit, in a small compass, for many years. Such trees are peculiarly proper for forcing, and not liable to canker." (Hort. Trans. vol. i. p. 65.) The cuttings are to be chosen from the young wood of horizontal or oblique branches, rather than from upright ones; from six to eight inches or more in length, with a small portion of old wood at
the lower end. Cut off the tip of the shoot, and all the buds, excepting two or three next the tip or upper extremity; then smooth the sections at the lower end, and insert them three or four inches in sandy loam, pressing the earth firmly to them, watering, and covering with a hand-glass. The proper time for this operation is early in February, and the glass should not be touched, excepting to give water, till the shoots have sprung an inch or two. Shade during the mid-day sun, and begin to harden by giving air in July; finally remove the glass in August; and in October transplant to nursery rows, or in pots, according to future intention. With the burknot tribe, all that is necessary is to plant the cuttings in a shady border, and treat them like those of the gooseberry or currant.

4385. By layers. The success of this mode of propagation may be considered as certain; as it has nothing peculiar in its application to the apple, we need only refer to general directions (1993.) for performing the operation. The after treatment of the plants is the same with that for those originated by the budding or grafting following modes.

4386. By suckers. This mode is generally confined to the paradise and creeping apple for stocks.

4387. By grafting and inoculation. This may be said to be the universal practice in propagating the apple. When inoculation is a perfect stock is used, the Stocking and wood must be free from any diseases. Scion as cutting, as used for full standards, and riders or wall standards; seedling crabs, for standards and half standards; codling apples, from layers or cuttings, for dwarfs and espaliers; paradise apples, or doucas, from layers or cuttings, for low dwarfs and trained; and creaper apples, from layers or cuttings, for the best dwarfs or bushes. Dubreuil, gardener at Rouen, recommends the doucin for clayey and light soils, and a free stock for such as are chalky and siliceous. (Hort. Trans. iv. 563.)

4388. Stools of seedling apples. The seeds should be selected from the fruit of vigorous growing young or middle-aged healthy trees; but when wanted in large quantities, they are procured from cider makers; private propagators will adopt the first mode. The sowing and after treatment is the same as for seedling crabs.

4389. Scion crabs. A preference, Knight observes, has generally and justly been given to apple-stem taken from the seeds of the native kind, or crab, as being more hardy and durable produced from the apple. The offspring of some varieties of the crab, particularly of those introduced from Siberia, vegetate much earlier in the spring than the other trees of the same species; and these the latter will probably be the first to support the weather. In this, however, he will be disappointed. The office of the stock is, in every sense of the word, subservient; and it acts only in obedience to the impulse it receives from the branches: the only qualities, therefore, requiring to be fitted for the purpose of stocks, are vigor and hardiness.

4390. Seeds, sowing, and culture. In recollecting the seeds to sow, it must be remembered, that the habits as well as the diseases of plants are often hereditary, and attention should be paid to the state of the parent tree from which the seeds are derived. This state should rather in a growing state than one of maturity or decay. The crab-trees, which stand in cultivated grounds, generally grow more freely and attain a larger stature than those in the woods, and therefore appear to claim a preference. The seeds should be taken from the fruit before it is ground for vinegar, and sown in beds of good mold. From these the seedlings should be taken out in late winter, and planted in rows at three feet distance from each other, and eighteen inches between each plant. Being here properly protected from cattle and hares, they may remain till they become large enough to be planted out; the ground being regularly worked and kept free from weeds. Codling stocks are raised chiefly from layers, which, at the end of the season, are taken off, and planted in nursery rows two feet between the rows, and one foot plant from plant.

4392. Paradise, or as they are called by the French, doucin stocks, are raised either from layers or suckers; and stocks from creeping apples (so named from their aptitude to throw up suckers), or the Dutch paradise, chiefly from the latter mode. They may be planted in nursery rows somewhat closer than the codling stocks.

4393. All stocks require to stand in the nursery till they are from half an inch to an inch thick, at the height at which they are to be grafted; such as are intended for full standards or riders will, in general, require to grow three or four years before being fit for this operation; those for half standards two years, and those for dwarfs one year. The ground between them must be kept clear of weeds, and stirred every spring; the shoots of the trees are sometimes rubbed off as they appear, and all suckers carefully removed. Where budding is adopted, the stocks may be worked at nearly half the diameter of stem requisite for grafting; and stocks for dwarfs planted in autumn or spring may be inoculated the succeeding summer. No great advantage, however, is gained by this practice, as such plants require to stand at least another year, before they have produced their bud-shoots.

4394. Soil and situation of the nursery. A difference of opinion appears always to have prevailed respecting the quality of the soil proper for a nursery; some have preferred a very poor, and others a very rich soil; and both perhaps are almost equally wrong. The advocates for a poor soil appear to me to have been misled by transferring the feelings of animals to plants, and inferring that a change from want to abundance must be agreeable and beneficial to both. But plants in a very poor soil become stunted and unhealthy, and do not readily acquire habits of vigorous growth, when removed from it. In a soil which has been highly manured, the growth of young apple-trees is extremely rapid; and their appearance, during two or three years, generally indicates the utmost exuberance of health and vigor. These are, however, usually the forerunners of disease, and the 'canker's desolating tooth' blasts the hopes of the planter. In choosing the situation for a nursery, too much shelter, or exposure, should be equally avoided; and a soil, nearly similar to that in which the trees are afterwards to grow, should be selected, where it can be obtained. Pasture ground, or unmanured meadow, should be preferred to old tillage, and a loam of moderate strength and of considerable depth to all other soils. (Ty. on App. and Pear.)

4395. Grafting. The first business is to select the scions, the principles of which have been already noticed (3043). At whatever season scions are to be inserted, Knight observes, the branches, which are to form them, should be taken from the parent stock during the winter, and not later than the end of the preceding year: for if the buds have begun to vegetate in the smallest degree, and they begin with the increasing influence of
the sun, the vigor of the shoots, during the first season, will be diminished, and the grafts will not succeed with equal certainty; though a graft of the apple-tree very rarely fails, unless by accidental injury, or great want of skill in the operator. The amputated branches must be kept alive till wanted, by having the end of each planted in the ground, a few inches deep in a shady situation.”

4396. Stocks destined to form standard trees, may either be grafted at the usual height at which the lateral branches are allowed to diverge, which is commonly six feet, or they may be grafted near the ground, and a single shoot trained from the graft, so as to form the stem of the tree. The propriety of grafting near the ground, or at the height of six or seven feet, will depend on the kind of fruit to be propagated, whether it be quite new and just beginning to bear, or a middle-aged variety. In new and luxuriant varieties, and these only should be propagated, it will be advantageous to graft when the stocks are three years old, as the growth of such will be more rapid, smooth, and upright than that of the crab, and there will be no danger of these being injured by beginning to bear too early. Middle-aged varieties will be most successfully propagated by planting stocks of six or seven foot high, and letting them remain ungrafted till they become firmly rooted in the places in which the trees are to stand. One graft only should be inserted in each stock; for when more are used, they are apt to divide when loaded with fruit, and to cleave the stock, having no natural bond or connection with each other. When the stocks are too large for a single scion, I would recommend that the grafts be inserted in the branches, and not in the principal stem. This practice is not uncommon in various parts of England; and is general in Germany, with free stocks, where, however, they often neglect to graft the trees; and thus, as Neill observes, produce an endless variety of sorts, some good, but most of them little better than crab.

4397. Stocks, intended to form half standards, are grafted at three or four feet from the ground; and those for dwarfs, at eight or ten inches, or lower. Miller and Knight agree in recommending to graft near the ground where lasting and vigorous trees are wanted; but the practice of the continental gardeners, and the observers of some in this country, are in favor of leaving a stem below the graft of not less than the full length.

4398. The kind of grafting generally adopted for moderate-sized stocks is the whip or tongue method (3088), or the new mode of saddle-grafting (3033) adopted by Knight; and the general time for the apple is the end of October and beginning of November. Much depends on the season and situation; the guiding principle is, to make choice of the time when the sap of the stock is in full motion; while that of the scions, from having been previously cut off and placed in the shade, is less so.

4399. The common season for budding the apple is July; as there is nothing peculiar to this tree in performing that operation, we refer to the general directions. (3065)

4400. Transplanting grafted trees in the nursery. “It has been recommended,” Knight observes, “to remove grafted trees once or twice during the time they remain in the nursery, under the idea of increasing the number of their roots; but I think this practice only eligible with trees which do not readily grow when transplanted. I have always found the growth of young apple-trees to be much retarded, and a premature disposition to blossom to be brought on by it; and I could not afterwards observe that those trees, which had been twice removed, grew better than others. It has also been supposed that many small roots, proceeding immediately from the trunk, are, in the future growth of the tree, to be preferred to a few which are large; but as the large roots of necessity branch into small, which consequently extend to a greater distance, the advantages of more transplantations than from the seed-bed to the nursery, and thence to the garden or orchard, may reasonably be questioned.”

4401. The choice of sorts depends on the object in view. The first thing an inexperienced gardener has to do is to consider the various domestic uses of the apple, and then determine what is wanted, according to the family or market to be supplied; the next thing is to consider how those wants may be supplied in his given soil, situation, and circumstances; and the last thing is to study the catalogue of sorts, and select accordingly. In every garden and private orchard, apples for ten different purposes are desirable:—

4402. For summer culinary use, as the

Cullings, while not fully grown or imperfectly ripe, which are fit for use in June, July, and August,

4403. For summer eating or table use, as the

Jennetings, penroy, &c., &c. which ripen in the end of June or in July | Margaret summer pearmain, &c., which ripen in July

4404. For autumn walking, as the

Codlings and Burbkott's, red streaks, English Golden Pippin, Golden Pippin, Doreen, &c., &c. which ripen in September

4405. For autumn table use, as the

Kirton and Dalnaboy pippins, Lean's pearmain, ovalite, Kent, gold-dolphin, &c., which ripen in September

4406. For winter culinary use, as the

Minier's dumpling, Burbkott, John apple, Mansfield tart, &c., &c. which are fit for December

4407. For winter table use, as the

Golden and Kentish pippins, golden and Canadian rennets, branded, &c., &c. which are fit to eat in December

4408. For spring culinary use, as the

Quince, white colville, Lord Cadbury's rennet, winter pearmain, &c., &c. which keep till the end of March

4409. For spring table use, as the

Spencer pippin, Trewidden rennet, Macdonald's Scotch nonpareil, Spaniard, &c., &c. which keep till the end of April
4409. For **spring table use, as the**
Hollow-eared, Cornwall remont, Hughie's
cockle new golden pippin, &c. which keep till
the end of June.

4410. For **summer culinary use, till the apple season returns, as the**
Lord Cherwell's green, Baxter's pearmain, stoup, coddling, &c. in
which keep till the end of June.

4411. For **summer table use, till the apple season returns, as the**
Dredge's fame, oakens peg, carnation, &c. which keep till the
end of June.

4412. **Other sources of choice.** Another source of the above, under each of the heads, may respect the
soil, situation, and climate of the garden, or orchard, in which they are to be planted, or the character, which
is important, as of dwarfs, espaliers, or wall-trees, which they are to assume there. The winter and spring table
apples may require a south wall in one district, while in another they may attain equal maturity as standards
or espaliers. Where there is ample room, a large number of large, as the Alexander and Baltimore apples, or
of dwarfed, or even beautifully cabled, the violet-flowered crab, may be made to gratify the eye, where
room is wanting, useful sorts and great bearers are to be preferred, as the golden and ribston pippin, summer
pearmain, codlings, grey russet, summer and winter colwhives, &c. In general, small-sized fruit, as the
Harveys and Granges, are to be preferred for standards, as less likely to break down the branches of
the trees, or be shaken down by winds; middling sorts for walls and dwarfs, and the largest of all for
espaliers. In respect to a soil liable to produce canker, sorts raised from cuttings may be desirable, as the
Burknot and codling tribe; and where an occupant of a garden has only a strong interest therein, such as
come into immediate bearing, as the Burknots, and others from cuttings, and the Hawthorndean, Apie's
apple, and other short-lived dwarf sorts on Paradise or creeping stocks, may deserve the preference. On the
contrary, where a planting is made on freehold property, or with a view to posterity, new varieties
on crab or free stocks, should always be chosen, as the Grange, Ingestrie, Harvey, &c. Some excellent
sorts and varieties, as the St. James, creamy, or Ribston, &c. the latter of which, Nicol says, will grow at
John O'Groat's house, and may be planted in Cornwall; others are shy bearers in cold situations, as the
Newtown pippin of America, and most of the newly imported French sorts.

4413. **Choice of plants and planting.** This depends in some degree on the object in view,
the richness of the soil, and the shelter; young trees are more likely to succeed in
exposed sites and poor soils, but the apple will bear transplanting at a greater age than
any other fruit-tree. It may be planted in any open weather from November till February.

4414. **Soil and site for permanent planting.** Any common soil, neither extremely
sandy, gravelly, nor clayey, on a dry sub-soil, and with a free exposure, will suit this
tree. On wet, hilly sub-soils, it will do no good, but after being planted a few years
will become cankered, and get covered with moss. Where fruit-trees must be planted
on such soils, they should first be rendered as dry as possible by under-draining; next,
provision made for carrying off the rain-water by surface gutters; and, lastly, the ground
should not be trenched above a foot deep, and the trees planted rather in hillocks of earth,
above the surface, than in pits dug into it. There is no point of more importance than
shallow trenching and shallow planting in cold wet soils, in which deep pits and deep
pulverisation only serve to aggravate their natural evils of moisture and cold. (Sang in
Caled. Hort. Mem. iv. 140.)

4415. Knight observes, that "the apple-tree attains its largest stature in a deep strong loam or marly
clay, and fruitful, will thrive in all rich soils, which are neither very wet at bottom. It succeeds best," he
adds, "in situations which are neither high nor remarkably low. In the former its blossoms are frequently
injured by cold winds, and in the latter by spring frosts, particularly when the trees are planted in the
lowest part of a confined valley. On the south, or south-east aspect is generally preferred, on account of the
blossoms being more open to the sun; on the north side, and especially where there is an amount of
frost, and where the violence of the west wind is broken by an intervening rise of ground, a south-west aspect
will be found equal to it." (Abercrombie's G. of G. ii. 215.)

4416. **Abercrombie says, all the sorts of apple-tree may be planted in any good common soil, with
a free exposure, whether that of a garden, orchard, or field; so that the ground be neither very low nor
excessively wet, nor subject to inundation in winter. Avoid, as far as possible, very strong clayey and gra-
velly." (Abercrombie.)

4417. **Mode of bearing.** In all the varieties of the common apple, the mode of bearing is upon small
terminal and lateral spurs, or short robust shoots, from half an inch to two inches long, which spring from
the younger branches of two or more years' growth, appearing first at the extremity, and extending gra-
dually down the side; the same bearing-branches and fruit-spurs continue many years fruitful." (Aber-
crombie.)

4418. **Pruning.** As, from the mode of bearing, apple-trees do not admit of short-
ening in the general bearers, it should only be practised occasionally: first, where any
extend out of limits, or grow irregular and deformed; and secondly, a good shoot con-
tiguous to a vacant space is shortened to a few eyes, to obtain an additional supply of
young wood from the lower buds of the shoot for filling up the vacancy. But to shorten
without such a motive, is not merely the cutting away of the first and the principal bear-
ning part of the branches, but also occasions their putting forth many strong useless wood-
shoots where fruit-spurs would otherwise arise; and both effects greatly tend to retard the
trees in bearing; whereas the fertile branches being cultivated to their natural length,
shoot moderately, and have fruit-spurs quite to the extremity." (Abercrombie.)

4419. **Espaliers and wall-trees require a summer and winter pruning.**

4420. **The summer pruning.** Train in the young shoots of the same year, which are likely to be wanted
in the figure, and trethen them where ill placed or too numerous; for as the trees continue bearing many
years on the same branches, they only require occasional supplies of young wood; therefore, begin in May
or June to pinch off or cut out close all fore-right, ill placed, and superfluous shoots; retaining only one
of the promising laterals in the more vacant parts, with a leader to each branch; train in these between
the mother branches, at their full length, all summer; or, where any vacancy occurs, some strong conti-
guous shoot may be shortened in June to a few eyes, to furnish several laterals the same season. Keep the shoots in all parts closely trained, both to preserve the regularity of the espalier, and to admit the air and sun to the advancing fruit.

4421. The winter pruning may be performed from November till the beginning of April. This comprehends the regularity of the wood-branches, the bearers, and of the young shoots. First, examine the new shoots trained in the preceding summer; and if too abundant, retain only a competency of well placed and promising laterals, to furnish vacant parts, with a leading shoot to each parent branch. Continue this examination of the full shoots as the pruning commences. Cut out, or prune short, all shoots that require it, and all shoots; and where any of the elder branches appear unfruitful, cankery, or decayed, cut them either clean out, or prune short to some good lateral, as may seem expedient. Also prune into order any branches which are very irregular, or too extended. Carefully preserve all the eligible natural fruit-spurs; but remove all unfruitful stumps and snags, and large projecting rugged spurs; cutting close to the old wood. As each espalier is pruned, let the old and new branches be laid in at convenient distances, according to the size of the fruit, four, five, or six inches asunder, and neatly tied or nailed to the wall or trellis. (Abencrombie.)

4422. Training espaliers. The following mode, as described by Mearns, is the most general, and by using stakes, which do not answer so well for any other species of espalier-tree as for apples, is also the most economical:—In the first stage of training, the stakes require to stand as close together as twelve or fourteen inches, and to be arranged in regular order to the full height of five feet, with a rail slightly fastened on the top of them for neatness sake, as well as to steady them. If stakes of small ash, Spanish chestnut, or the like, from coppices or thinnings of young plantations, be used, they will last for three or four years, provided they are from one inch and a half to two inches in diameter, at a foot from the bottom. They need not be extended further in the first instance than the distance to be considered probable the trees may reach in three years’ growth; at that period, or the following season, they will all require to be renewed, and the new ones may be placed on each side, to the extent that the trees may be thought to require while the growth of the spars, and when that is intended, the leader should be left a little longer, to allow of its being bent. In espalier training this zigzagging is not so readily done, nor is it necessary where the trees are not intended to rise high. It is always necessary, in the course of training the young wood across the stakes, to plant the main laterals, to tie them to the rails, in order to guide the shoots of the year in a proper direction. The proper ties are small osier twigs.

4423. The following summer encourage three other shoots in the same way as the season before (c), then cut off the middle shoot at ten, twelve, or fifteen inches above the base of the other two, and train these last in the following season (e) and so continue training. (Mearns, in Hort. Trans. v. 46.) An improvement on this mode consists in cutting down the leading shoot during summer, in the manner practised by Harrison, of Wortley Hall, as described in the succeeding paragraphs.

4426. Training against a wall. The horizontal mode is unquestionably to be preferred for so vigorous a growing tree as the apple; and Harrison’s mode of conducting the process (Tr. on Fruit-Trees, 1823. ch. xx.) appears to us much the best. The peculiarity of his method is, that instead of training the leading shoot in a serpentine or zigzag manner with Hitt or Mearns, to make it send out side shoots, he adopts the much more simple and effectual mode of cutting down the current year’s shoots in June; by which means he gains annually a year, as side shoots are produced on the young wood of that year, as well as on last year’s wood which it sprang from.

4427. The tree being a maiden plant is the first year headed down to seven buds. Every bud pushing, two of the shoots, the third and fourth, counting upwards, must be rubbed off when they are three inches in length; the uppermost shoot must be trained straight up the wall for a leading stem, and the remaining four horizontally along the wall. The leading shoot having attained about fifteen inches in length, cut it down to eleven inches. From the shoots that will thus be produced select three, one to be trained as a leader, and the other two to be grazed off. In this way for three seasons, the tree will reach the top of a wall twelve feet high. With weak trees, or trees in very cold late situations, this practice will not be advisable, as the wood produced would be too weak, or would not ripen; but in all ordinary situations, it is obviously a superior mode to any that has been hitherto described in books. In pruning the spurs of apple trees, or other trees, Harrison differs from many gardeners in keeping them short, never allowing one spur to have more than three or four fruit-buds, and in cutting off the spurs entirely, or cutting them down for renewal every fourth or fifth year. Every practical gardener, desirous of excelling in the training and spurring of fruit-trees, ought to possess Harrison’s treatise.

4428. Heading down apple-trees that are much cankered, is strongly recommended by Forsyth, who gives an example of one (fig. 484.), after it had been headed down four years, which bore plenty of fine fruit. The point at which it was headed down (a) was within eighteen inches of the soil; and under it, on the stump, were two large wounds (b)
and (c), made by cutting out the canker part, and which being covered with the composition were soon nearly filled up with sound wood. Very little pruning is at first given to trees so cut, but afterwards a regular succession of bearing wood is kept up by removing such as have borne for three or four years. Thus, one branch (d), which has done bearing, is cut off, and succeeded by another (f), and when that is tired also, it is cut off, and replaced by a third (e), and so on.
water, together with amputation when it has been some time at work, is the only means of destroying this insect; but even this will not do, unless resorted to at an early stage of its progress. The caterpillars of many species of butterfly and moth, and the larvae of various other genera of the hemiptera and lepidoptera, &c. as Scarabeaus, Cuculli, &c. attack the apple-tree in common with other fruit-trees; and on a large scale it is difficult, if not impracticable, to avoid their injurious effects. Burning straw or other materials under the trees has been long recommended; but the principal thing to be relied on, in our opinion, is regimen; that is, judicious sub-soil and surface soil, culture, and pruning.

4432. Other points of culture have been already given. See Chap. II. and III. and for gathering and storing the crops, see Chap. IV. Sect. X. and Chap. V. Sect. III.

4433. The pear-tree, in its wild state, is a thorny tree, with upright branches, tending to the pyramidal form, in which it differs materially from the apple-tree. The twigs or spray hang down; the leaves are elliptical, obtuse, serrate; the flowers in terminating villose coryms, produced from wood of the preceding year, or from buds gradually formed on that of several years' growth, on the extremities of very short protruding shoots called, technically, spurs. It is found in a wild state in England, and abundantly in France and Germany, as well as other parts of Europe, not excepting Russia, as far north as lat. 51. It grows in almost any soil. The cultivated tree differs from the apple, not only in having a tendency to the pyramidal form, but also in being more apt to send out tap-roots; in being, as a seedling plant, longer (generally from fifteen to eighteen years) of coming into bearing; and when on its own root, or grafted on a wild pear-stock, of being much longer lived. In a dry soil it will exist for centuries, and still keep its health, productiveness, and vigor. "The period at which the teinton squash first sprang from the seed, Knight observes, probably, cannot be at all ascertained; but I suspect, from its present diseased and worn-out state, that it existed at least as early as the beginning of the sixteenth century: for another kind, the barland, which was much cultivated in the early part of the seventeenth century, still retains a large share of health and vigor; and the identical trees which supplied the inhabitants of Herefordshire in the seventeenth century with liquor, are likely to do the same good office to those of the nineteenth." Our remarks on the history of the apple will apply almost without exception to the pear. The Romans, in Pliny's time, possessed thirty-six varieties, and the fruit is still more valued, both in Italy and France, than the apple.

4434. Use. As a dessert fruit the pear is much esteemed, and generally preferred to the apple. It is also used for baking, compotes, marmalade, &c. Pared and dried in the oven, the fruit will keep several years, either with or without sugar. This mode of preparing the pear is about as common in France as the making of apple-pies is in this country; and what is favorable to the practice is, that bad eating sorts answer best for drying. Bosc (Nouveau Cours d’ Agric. in loco) describes two methods of drying pears for preservation; and adds, that he has tried them after three years' keeping, and found them still very good. Perry, the poiré of the French, is made from the fermented juice, in the manner of cider, and the best sorts are said by Withering to be little inferior to wine. The wood of the pear-tree is light, smooth, and compact, and is used by turners, and to make joiners' tools, picture-frames to be dyed black, &c. The leaves will produce a yellow dye, and may be used to give a green to blue cloths.

4435. Criterion of a good pear. Dessert pears are characterised by a sugary aromatic juice, with the pulp soft and sub-liquid, or melting, as in the beurrés, or butter-pears; or of a firm and crisp consistence, or breaking, as in the winter bergamots. Kitchen pears should be of large size, with the flesh firm, neither breaking nor melting, and rather austere than sweet, as the wardens. Perry pears may be either large or small; but the more austere the taste, the better will be the liquor. Excellent perry is made from the wild pear.

4436. Varieties. Tusser, in 1573, in his list of fruits, mentions "peears of all sorts." Parkinson enumerates sixty-four varieties; Mortimer, in 1708, has many sorts; and Miller has selected eighty sorts, and described them from Tournefort. In France, the varieties of the pear are much more numerous than even the varieties of the apple. The catalogue of the Luxemburg nursery at Paris contains 189 select sorts. The British nursery lists at the present time contain from two to three hundred names, among which, it may be observed, the number of good sorts are fewer in proportion than in the apple lists. In the present very imperfect state of the nomenclature of fruits, all we can do is to make a selection from names which have some descriptive particulars attached. We shall arrange them into dessert, kitchen, and perry pears, and each tribe shall be set down in the order of their ripening.

### KITCHEN PEARS — Arranged in the order of their ripening.

- Amuse, eustere
- Yellowish
- Red and yellow
- Handsome, upright tree; strong shoots
- A beautiful fruit
- Excellent to preserve, taking a fine red color from the fire
- Free-growing, upright tree
- Hardy standard tree
- Very austere
- Very austere
- Very austere

4438. Propagation. The pear may be propagated by layers or suckers, but not easily by cuttings. These modes, however, are productive of very indifferent plants, and are justly rejected in favor of raising from seed, and grafting or budding.

4439. From seed. This mode is adopted either for the purpose of obtaining new varieties, or for producing pear-stocks. In the former case, the same principles of selection or crossing are to be followed which we have stated in treating of raising seedling apple-trees, between which and the pear-tree, the differences are equally great, and as to time, it is only requisite, to consider that the proportion of good sorts to bad, so originated, is but very small. Professor Van Mons, proprietor of the Pépinière de la Fidélité, at Brussels, has upwards of 800 approved sorts of new pears, raised from seed by himself and M. Duquesne, of Mons, in the course of fifteen or sixteen years, and selected from, probably, 8000 new seedling fruits. Van Mons observed to Noll, that "he seldom failed in procuring valuable apples from the seed; for those which were not adapted to the garden as dessert fruit, were probably suited for the orchard, and fit for baking or cider-making. With pears the case was different, namely."

4440. In raising pears for stock, the seeds from perry-makers are generally made use of; but the most proper are those from the wild pear, as likely to produce plants more hardy and durable. There is, however, less difference between free pear-stocks, for those raised from the cultivated fruit, and wild pear-stocks, than there is between free apple and crab-stocks. The seeds being procured, may be sown, and afterwards treated as directed for seedling crab, or apple-tree stocks.

4441. From the wild pear-stocks for grafting, the pear are the common pear and wilding; but as the apple is dwarfed, and brought more early into a bearing state by grafting on the paradise or creper, so is the pear by grafting on the quince or white-thorn. The pear will also succeed very well on the whitebeam, medlar, service, or apple, but the wilding and quince are in general use. Pear-stocks of trees growing luxuriantly on a dry bottom, or even in bare fields, may be used, but are deemed more curable, and they will thrive on the poorest soil, if a hardy variety, and not over-pruned. "On the quince," Miller observes, "breaking pears are rendered gritty and stony; but the meting sorts may be planted in a most soil with British as those on wildings or thorns." On the pond, pears come very early into bearing, continue prolific, and, in respect to soil, will thrive well on a strong clay, which is unsuitable both to those on quinces and wildings; but they are supposed to have an unfavorable influence on the fruit, in rendering it smaller and hard; and the grafts or buds require to be inserted very low, that the moisture of the earth may tend to favor the swelling or enlargement of the diameter of the stock, which does not increase proportionally to, nor ever attains the same size as the stem of the pear. Dubreuil, a French gardener, recommends the quince as a safer stock for pears, than the pear, (Horticul. Tour, 3rd ed., 308.) The free and wilding pear-stocks are to be planted in nursery rows, at the same distance as recommended for free and wilding apples; and the quince and thorn at the same distance as the paradise and creeper apples; in other respects, the management is the same as for the apple.

4442. Choice of sorts. (See Ch. II. and III. on Planting the Orchard and Kitchen-Garden.) The following is a list of table-pears for use in succession, from July to July again, as furnished for the table of the Duke of Buccleugh from the Dalkeith garden.

The letters mark the aspect of the walls against which they are trained.

(W) Jargonette.
(S) Autumn bergamot.
(W) General's bergamot.
(S) Summer bergamot.
(W) Winter bergamot.
(W) Summer bonchretten.
(S) Summer acan.
(S) Green achat.
(S) Longch. (W) Winter bonchretten.
(W) St. Germain.
(S) Green wine pear.
(W) Brown baccare.

4443. Choice of plants. Abercrombie takes trees at one year from the graft, and thence to the sixth year; or even to trees who into the sixth year, if the roots of those young ones, to look for out the oldest that they can find in the nursery, and with strong stems.

4444. Soil and site. "A dry, deep loam," Abercrombie observes, "is accounted the best soil for the pear-tree when the stock is of its own species; on a quince-stock it wants a moist soil, without which it will not prosper. Gravel is a good-soil, where the incubent mould is suitable. Cold clay is a bad sub-soil; to prevent fruit-trees from striking into it, slates may be laid just under the roots. For wall-trees, the soil should be made good to the depth of three feet; for orchard-trees, eighteen inches may do. Pear-trees, except where apple-trees are planted, should not be hardy varieties, little removed from wildings, and to have room to grow freely as standards. To the more choice of the early autumn and prime winter pears, assign south, cast, or west walls. Knight and McPhail recommend a strong, deep, loamy soil, and the latter a high wall for training the better sorts." (Gregor's hort., 1836.)

4445. Grafting. In mild weather, from October to March; standards are placed from twenty-five to forty feet apart every way; half standards, from twenty to thirty; and dwarf standards, in borders from fifteen to twenty feet from stem to stem. Wall and espalier trees are planted from fifteen to thirty feet apart, according as they may have been planted on pear or quince-stocks.

4446. Mode of bearing, as in the apple-tree. "The pear-tree," McPhail says, "does not produce blossoms on the former year's wood, as several other sorts of trees do. Its blossom-buds are formed upon spurs growing out of wood not younger than one year old, and consequently, projecting spurs all over the tree must be left for that purpose." In some pears, "the fruit is only on the inside of those branches which are exposed to the sun and air; in others it occupies every part of the tree." (Gregor's hort., 1836.)

4447. Pruning and training standards. "Permit these to extend on all sides freely, several years may elapse before any cross-placed, very irregular, or crowded branches, dead and worn-out bearers, require pruning, which give in winter or spring. Keep the header moderately open in the middle." "Pruning," Knight observes, "is not often wanted in the culture of the pear-tree, which is rarely much encumbered with superfluous branches; but, in some kinds, whose form of growth resembles the apple-tree, it will sometimes be found beneficial."
4448. *Pruning and training wall-trees.* As a wall-tree or espalier, the pear is always trained in the horizontal manner on account of its luxuriant growth. Harrison trains most pear-trees in this way, and proceeds exactly as he does in training the apple-tree. (4427) But, "when it occurs that a tree trained after this method still continues unfruitful for several years after planting, the branches must be trained in a pendulous manner, and more or less so, according to the luxuriance of the tree, but always commence the training in the horizontal method, and afterwards change the direction of the branches as required." (Tr. on *Fruit Trees*, 144.) The ordinary distance at which he trains the side shoots is nine or ten inches, but the jargonnele he lays in at twelve inches, so as to have room for laying in side shoots from the spurs, for one or more years. This he finds keeps the luxuriance of the tree, and keeps it in full bearing. (Tr. on *Fruit Trees*, 159.)

4449. Forsyth, in training a young pear-tree, shortens the leading shoot in March, and when the shoots it produces are very strong, he says, "I cut the leading shoot twice in one season; by this method I get two sets of side shoots in one year, which enables me the sooner to cover the wall. The second cutting is performed about the middle of June." (Tr. on *Fruit Trees*, 193.)

4450. *Established wall-trees and espaliers* will require a summer and winter pruning, and the following are Abercrombie's directions: —

4451. *Summer pruning.* While the spray is young and soft, but not until the wood-shoots can be distinguished from the grass, rub off the suckers, rub the diseased parts of the year, rather than let them grow woody, so as to require the knife. Retain some of the most promising, well placed, lateral, and terminal shoots, always keeping a leader to each main branch, where the space will permit. Leave the greater number on young trees not fully supplied with branches. Train in these at the same time. In the following year, choose a few branches, either temporarily or occasionally on old trees, or others, where any considerable vacancy occurs, some principal contiguous shoot may be shortened in June to a few eyes, for a supply of several new shoots the same season.

The winter pruning may be performed any time from the beginning of November until the beginning of April. If on young trees, or others, further pruning is required to fill up either the prescribed space, or any casual vacuity, retain some principal shoots of last summer, to be trained for that purpose. As, however, many young shoots will have arisen on the wood-branches and bearers, of which a great part are redundant, and which may become disorderly, we have resolved to prune as necessary, either momentarily, or, in the winter, a pruning, we must now cut these out close to the mother branches, while we are preserving the best in the more open parts. Examine the parent branches, and if any are very irregular, or defective in growth, either cut them out close, or prune them to some eligible lateral to supply the place; or if any branches become so heavy that they may be made serviceable in such order, or size, as is necessary, remove the regular of the too crowded; also any casually declined bearers; with decayed, cankerly, and dead wood. The retained supply of laterals and terminals should be laid as much at length as the limits allow, in order to furnish a more abundant quantity of fruit-buds. During both courses of pruning it is advisable to be careful in the use of the axe, that no fruit-sprout permitted to grow to a more than a small degree, in which case it is advisable to branch it at once. It is also advisable to preserve all the orderly fruit-spurs emitted at the sides and ends of the bearers: if, however, any large, rugged, projecting spurs, and woody barren stumps or snags occur, cut them clean away close to the branches, which will render the bearers more productive of fruit-buds, and regular in appearance. As each tree is pruned, nail or tie the branches and shoots to the wall or trellis. If afterwards, in consequence of either pruning out improper or decayed wood, or of former insufficient training, there are any material vacuities or irregularities in the arrangement, un-nail the misplaced and contiguious branches, and let them fall in order.

4492. *Knight's mode of training the pear-tree* is as follows: "A young pear-stock, which had two lateral branches upon each side, and was about six feet high, was planted against a wall early in the spring of 1810; and it was grafted in each of its lateral branches, two of which sprang out of the stem, almost on a level with the ground, and the other at its summit in the following year. The shoots these grafts produced, when about a foot long, were trained downwards, the undermost nearly perpendicularly, and the uppermost just below the horizontal line, placing them at such distances that the lengths of one shoot did not at all shade those of another. In the next year, the same mode of training was continued. The following year, an attempt was made of the spurious kind, had been trained in the fan-form, against a north-west wall in my garden, and the central branches, as usually happens in old trees thus trained, had long reached the top of the wall, and had become wholly unproductive. The other branches afforded but very little fruit, and that never acquiring maturity, was consequently of no value; so that it was necessary to change the variety, as well as to render the tree productive. To attain these purposes, every branch which did not want at least twenty degrees of being perpendicular, was taken out at its base; and the spurs upon every other branch, which I intended to retain, were taken off closely with the saw and chisel. Into these branches, at their subdivisions, grafts were inserted at different distances from the root, and some so near the extremities of the branches, that the tree extended as widely in the autumn, after it was grafted, as it did in the preceding year. The grafts were also so disposed, that every part of the space the tree was to fill up, was filled with very strong shoots. As soon as the young shoots had attained sufficient length, they were trained almost perpendicularly downwards, between the larger branches and the wall to which they were nailed. The most perpendicular remaining branch, upon each side, which was four feet from the top of the wall, which is twenty feet high, and the young shoots, which the grafts upon these afforded, were trained inwards, and bent down to occupy the space from which the old central branches had been taken away; and therefore very little vacant space any where remained in the end of the first autumn. A few blossoms, but not any fruit, were produced by several of these grafts in the succeeding spring, but in the following year, and subsequently, I have had abundant crops, equally dispersed over every part of the tree."
4454. **Harrison**, and various other gardeners, adopt the mode of keeping only short spurs, by which much larger fruit is produced. According to this plan, each spur (fig. 487. a) bears only once, when it is cut out, and succeeded by an embryo-bud (d) at its base. This bud at the end of the first season, is no more than a leaf-bud (c); but at the end of the second summer, it has become a blossom-bud (b), and bears the third summer (a). Some useful observations on the management of pear-trees, in correspondence with Harrison's practice, will be found in different parts of the Caledonian Hort. Memoirs, vol. i.

4455. **Forsyth** says, "The constant practice has been to leave great spurs as big as a man's arm, standing out from the walls, from one foot to eighteen inches and upwards. The constant pruning of these brings on the canker; and by the spurs standing out so far from the wall, the blossom and fruit are liable to be much injured by the frost and blighting winds, and thus the sap will not have a free circulation all over the tree. The sap will always find its way first to the extremities of the shoots; and the spurs will only receive it in a small proportion, as it returns from the ends of the branches." (Tr. on Fruit Trees, 187.)

4456. **Setting the fruit.** In a very curious paper on this subject, by the Rev. G. Swayne, he informs us of a pear-tree, which had for twenty years never borne fruit, but which he induced to bear by cutting off all the blossoms of each corymbus of flowers, excepting the lower three, on the same principle as gardeners top-beans. This succeeded to a certain extent on one tree, but not on another; the selected blossoms of the other he rendered fruitful by cross-impregnation. He says, "I fancied likewise that the pedotal was fit for impregnation before the anthers were ripe, and even before the petals expanded; and from the peculiarly slender and delicate make of the latter, as it struck me, I supposed, that it ceased to be in a proper state as soon as it became exposed to the sun and air; I therefore concluded, that there might possibly be a chance of obtaining fruit, by depriving the blossoms of their petals before they expanded, and enclosing with each floret in this state, within a paper envelope (as is my mode of effecting artificial impregnation), a riper blossom, viz. one that had just began to diffuse its farina, either one of its own, or, preferably, of some other variety of pear." (Hort. Trans. v. 210.) He tied up twenty-seven envelopes on the 27th of March, and took off the papers on the 15th of April; a number succeeded, and produced ripe fruit, specimens of which were sent to the Horticultural Society, and found unusually large and handsome. The Rev. Experimenter concludes his paper, by observing, "whether the result of the above detailed experiments be such as to authorize an expectation that artificial assistance in vegetable fecundation, will hereafter become of so much importance to gardeners, in the instance just alluded to, as in those at present recognised, of the cucumber, the melon, the early bean, and the hauftobis straw-berry, must be left to futurity to ascertain." (Hort. Trans. v. 212.)

4457. **Harrison** appears to have adopted a similar practice, he says, "It is very general to see healthy pear-trees, which produce an abundance of bloom but set a very small proportion of fruit; this is more particularly the case with the tenderest kinds. The reason of such barrenness is in some cases from the stamina being destitute of farina, and in others from the farina having been dispersed before the pistillum had arrived at a proper state for its reception. To remedy such defects, I adopt the following practice. As soon as the florets have expanded and the pistillum is in a proper state of maturity, I impregnate six upon each corymb of blossom. The florets which I choose for this operation are those situated nearest the origin of the spur, for when pears set naturally, it is very generally such florets. The time I choose for this operation is calm dry days, and if possible when the sun is not very hot upon the trees. Immediately after performance, I give each tree about eighteen gallons of manure water, or soft pond water, at the roots. The trees should never be washed over the tops for a considerable time after this impregnation has been effected." (Tr. on Fruit Trees.)

4458. **Insects, diseases, &c.** The pear-tree is liable to the attacks of the same insects.
as the apple-tree; and the fruit of the summer kinds, when ripe, is liable to be eaten by birds, wasps, &c. which must be kept off by shooting, hanging bottles of water, and other usual preventives.

For other points of culture, and gathering and storing, see Chap. II., Chap. IV. Sect. IX., and Chap. V. Sect. III.

4459. The quince-tree is of low growth, much branched, and generally crooked and distorted. The leaves are roundish or ovate, entire, above dusky-green, underneath whitish, on short petioles. The flowers are large, white, or pale-red, and appear in May and June; the fruit, a pome, varying in shape in the different varieties, globular, oblong, or ovate; it has a peculiar and rather disagreeable smell and astringent taste. It is a native of Austria and other parts of Europe; is mentioned by Tusser, in 1753; but has never been very generally cultivated.

4460. Use. The fruit is not eaten raw; but stewed, or in pies or tarts, along with apples, is much esteemed. In confectionary, it forms an excellent marmalade and syrup. When apples are flat, and have lost their flavor, Forsyth observes, a quince or two, in a pie or pudding, will add a quickness to them. In medicine, the expressed juice, repeatedly taken in small quantities, is said to be cooling, astringent, and stomachic, &c. A mucilage prepared from the seeds was formerly much in use, but is now supplanted by the simple gums. In nursery-gardening, the plants are much used as stocks for the pear.

4461. **Varieties. Miller enumerates** —

| The oblong, or pear-quince; with oblong ovate leaves, and an oblong fruit lengthened at the base. | with obovate leaves, and an oblong fruit, which is more juicy and less harsh than the others, and therefore the most valuable. It is rather a shy bearer, but is highly esteemed for marmalade, as the pulp has the property of assuming a fine purple tint in the course of being prepared. |

| The apple-quince, with ovate leaves and a rounder fruit. | The Portugal quince (Long. Prov. t. 75),... |

4462. **Propagation.** Generally by layers, but also by cuttings, and approved sorts may be perpetuated by grafting. In propagating for stocks, nothing more is necessary than removing the lower shoots from the larger, so as to preserve a clean stem as high as the graft; but for fruit-bearing trees, it is necessary to train the stem to a rod, till it has attained four or five feet in height, and can support itself upright.

4463. **Sowing and site.** The quince prefers a soft moist soil, and rather shady, or, at least, sheltered situation. It is seldom planted but as a standard in the orchard, and a very few trees are sufficient for any family.

4464. The time of planting, the mode of bearing, and all the other particulars of culture, are the same as for the apple and pear.

4465. The medlar is a small or middle-sized branching tree; the branches woolly, and covered with an ash-colored bark, and, in a wild state, armed with stiff spines. Leaves oval-lanceolate, serrate, towards the base somewhat woolly, on very short channelled petioles.

Flowers produced on small natural spurs, at the ends and sides of the branches. Bracts as long as the corolla; calyxes terminating, fleshy; petals, white; fruit, a turbinate berry, crowned with five calyceal leaflets; pulp thick, mixed with callose granules, and containing five gibbous wrinkled stones. The tree flowers in June and July, and the fruit is ripe in November. It is a native of the south of Europe; but appears to be naturalised in some parts of England, where it has been sown in copses by birds.

4466. Use. The fruit is eaten raw in a state of incipient decay; its taste and flavor are peculiar, and by some much esteemed.

4467. **Varieties.** Those in common cultivation are —

| The Dutch medlar (Post. Flora. 2, p. 45. t. 2, 51;) a crooked, deformed, low tree with very large leaves, entire, and downy on the under side. The flowers and fruit are very large; the latter approaching to the shape of an apple. | The wild medlar; a smaller tree, with smaller leaves, flowers, and fruit than any of the former sorts, and the fruit in pear-shaped. |

| The Nottingham medlar; with fruit of a quicker and more poignant taste. | The wild medlar; a smaller tree, with smaller leaves, flowers, and fruit than any of the former sorts, and the fruit in pear-shaped. |

4468. **Propagation.** By seeds, by layers, and cuttings, or by grafting on seedlings of their own species, or on any other species of mespilus, or of cydonia, or cranagees. Miller observes, that if the stones are taken out of the fruit as soon as it is ripe, and immediately planted, they will come up next spring, and make good plants in two years. He prefers raising from seed to grafting on the cranagees. Forsyth says, “Those who wish to keep the sorts true, should propagate them by grafting on their own stocks.” The plant is rather difficult to strike by cuttings.

4469. **Soil.** The soil in which the medlar thrives best is a loamy rich earth, rather moist than dry; but not on a wet bottom.

4470. **Final planting.** The medlar, like the quince, is usually grown as a standard or espalier; the former may be planted from twenty to thirty, and the latter from fifteen to twenty feet apart.

4471. **Mode of bearing.** On small spurs at the ends and sides of the branches.

4472. **Pruning.** Forsyth recommends the same sort of treatment as for the quince. Cut out all the dead and cankerly wood, and keep the tree thin of branches when it is desired to have large fruit. Care is requisite to train standards with tall stems. Espaliers will require a summer and winter pruning, as in the apple-tree.

For other details of culture, see the Apple and Pear.

4473. The true-service-tree is of the middle size, not unlike the mountain-ash, of a very low growth, and not flowering till it arrives at a very great age. The leaves are compound, alternate, with ovate or oval leaflets. The flowers are produced on terminating panicles issuing from spurs of two or more years' growth; the petals are cream-colored; the fruit, according to Gaertner, is a pome, pear-shaped, reddish, and spotted, extremely astringe, and not eatable till it is quite mellowed by frost or time, when it becomes brown and very soft. It flowers in May, and the fruit ripens in November; the tree, according to Krocken, does not come into full bearing before it is sixty years old. It is a native of the warmer parts of Europe, and has also been found wild in Cornwall, Worcestershire, and Hertfordshire, from whence the fruit is brought to London in autumn in large quantities. Miller says, “There was one tree in the garden of John Tradescant, of South Lambeth, near forty feet high, which produced a great quantity of fruit annually, shaped like pears. Some trees of middling growth, in the garden of Henry Marsh, Esq. at Hammer smith, produced fruit of the apple-shape. From these many trees were raised in the nurseries near London, but the fruit was small compared with that of Tradescant.” Great numbers of large service-trees grow wild about Aubigny in France; from the seeds of which one of the dukes of Richmond raised a great many trees at Goodwood in Sussex. It is a very common fruit-tree at St. Germans en Laye, where it is cultivated along with Pyrus Americana.

4474. Use. The fruit has a peculiar acid flavor, and is eaten, when mellowed, like that of the medlar, to which it is deemed inferior. It is common in Italy, and ripens at Genoa in September, where it is esteemed good in dysentery and fluxes. The wood, which is very hard, is held in repute for making mathematical rulers, and excisemen's gauging-sticks.

4475. Varieties. In Italy they have many varieties obtained from seeds; but those generally known here are only three; the pear-shaped, apple-shaped, and berry-shaped.

4476. Propagation. By seeds, cuttings, or layers; or, which is preferable for plants intended to form good-sized and early-bearing trees, by grafting on seedlings of their own species. It may also be grafted on the pyrus, moschus, or drupas.

4477. Soil. The best is a strong clayey loam.

4478. Culture. The tree is recommended by Forsyth and Abererombe to be grown as a standard at twenty or thirty feet distance, and to be pruned and otherwise treated like the apple and pear. Choice sorts, Abererombe observes, are sometimes trained as dwarf standards, or espaliers.

4479. Gathering the crop. It is late in autumn before this operation can be performed. Wipe the fruit dry, and lay it on dry wheat-straw, spread on the open shelves of the fruit-room. In about a month it will become mellow and fit for use. See Chap. IV. Sect. X. and Chap. V. Sect. III.

Sect. II. Stone-Fruits.

4480. Of stone-fruits the most esteemed is the peach tribe, and next the apricot; both the trees natives of Persia, but acclimated in Britain, and remarkable for the lively colors and early appearance of their blossoms. The peach is one of the most delicious of summer fruits. Besides the peach, nectarine, and apricot; the almond, plum, and cherry, are comprehended in this section.

4481. The peach-tree in its natural state is under the middle size, with spreading branches, lanceolate, smooth, and serrated leaves. The flowers are sessile, with reddish calxies, and bell-shaped, pale or dark-red corollas, often bordered with purple; the fruit a roundish drupe, generally pointed, and with a longitudinal groove; pulp, large, fleshy or succulent, white or yellowish, sometimes reddish, abounding with a grateful, sweet, acid juice; stone, hard, irregularly furrowed; kernel, bitter. The tree of quick growth, and not of long duration; blossoms in April, and ripens its fruit in August and September. Sickler considers Persia as the original country of the peach, which, in Media, is deemed unwholesome; but, when planted in Egypt, becomes pulpy, delicious, and salubrious. The peach also, according to Columella, when first brought from Persia into the Roman empire, possessed deleterious qualities; which Knight concludes to have arisen from those peaches being only swollen almonds (the tuberes of Pliny), or im-
perfect peaches; and which are known to contain the Prussian acid which operates unfavorably in many constitutions. The tree has been cultivated time immemorial in most parts of Asia; when it was introduced into Greece is uncertain: the Romans seem to have brought it direct from Persia, during the reign of the emperor Claudius. It is first mentioned by Columella, and afterwards described by Pliny. The best peaches in Europe are at present grown in Italy on standards; and next may be cited those of Montreuil, near Paris, trained on lime-whited walls. (Mozard, sur l’Éducation des arbres à Fruits, et principalement du Pêcher, &c. 1814.) We visited these gardens in May, 1819, and examined more particularly those of Jean Pierre Savard, the principal propriétaire cultivateur. His trees were that season covered with aphides, and the principal part of treatment in which he seemed expert was that of varying the position of the branches of the tree every year, by elevating to a greater angle the weak, depressing the strong, and cutting out the old, naked, or twigless shoots; thus presenting at all times a well balanced tree. The stems of these trees, when first planted, and for one or two years afterwards, are hooked to the wall, to prevent their being stolen! Mozard’s garden was visited by the Caledonian Horticultural deputation in 1817, who found wholesome management, but nothing new. In England, there are but few sorts of peaches that come to tolerable perfection in the open air, in ordinary seasons. The best adapted for this purpose are the free stones; but all the sorts ripen well by the aid of a hot-wall or glass, and may be forced so as to ripen in May or June. The tree is generally an abundant bearer; one of the noblest kind, at Yoxfield, in Suffolk, which covers above six hundred square feet of trellis under a glass case, without flues, ripens annually from sixty to seventy dozen of peaches. (Hort. Trans. iii. 17.)

4482. Use. It is a dessert fruit, of the first order, and makes a delicious preserve. In Maryland and Virginia a brandy is made from this fruit. "The manufacture of this liquor, and the feeding of pigs, being," as Braddock observes (Hort. Tr. ii. 205.), "the principal use to which the peach is applied in those countries." The leaves, steeped in gin or whiskey, communicate a flavor resembling that of noyeau.

4483. Criterion of a good peach. A good peach, Miller observes, possesses these qualities: the flesh is firm; the skin is thin, of a deep or bright red color next the sun, and of a yellowish-green next the wall; the pulp is of a yellowish color, full of high-flavored juice; the fleshy part thick, and the stone small.

4484. Varieties. Linnaeus divides the A. Persica into two varieties; that with downy fruit or the peach, and that with smooth fruit or the nectarine. There are various instances on record (Hort. Trans. vol. i. p. 103.) of both fruits growing on the same tree, even on the same branch; and one case has occurred of a single fruit partaking of the nature of both. The French consider them as one fruit, arranging them in four divisions: the pêches, or free stone peaches, the flesh of whose fruit separates readily from the skin and the stone; the pêches lisse, or free stone nectarines, or free stone smooth peaches; the pavés, or cling-stone peaches, whose flesh is firm and adheres both to the skin and stone; and the brugnons, or nectarines, or cling-stone smooth peaches. Knight (Hort. Tr. iii. 1.), Robertson (Hort. Tr. iii. 382.), and various botanists, consider the peach and almond as one species.

4485. The flat peach of China (Hort. Trans. vol. iv. pl. 19.) is a curious flattened fruit (fig. 489.), sweet and juicy, and with a little noyeau flavor. Knight has fruiteted it, and considers that from the early habits of the tree it will prove a valuable acquisition. He has "found excitability of habit to be hereditary in the seedling offspring of plants, and to be transferable by the pollen;" and, therefore, imagines "there will be no difficulty in obtaining from the flat peach other varieties of similar habits, free from the deformity which has recommended it to the Chinese." (Hort. Trans. v. 272.)

4486. There are many fine varieties of the peach: Tusser, in 1573, mentions peaches, white and red; Parkinson, in 1629, enumerates twenty-one; and Miller, in 1750, thirty-one varieties. In the garden of the Luxemburg, at Paris, are seventy varieties; and above double that number of names are to be found in the catalogues of our nurseries. Three distinguished and ingenious attempts have been made to class the varieties of peaches and nectarines, by the leaf and flower as well as the fruit: the first is by Poiteau, in the Bon Jardinier; the next by Count Leliour, in his Pomone Francaise; and the third by Robertson, nurseryman, of Kilkenney, whose arrangement is founded on the glands of the leaves. But as these systems are not yet sufficiently perfected to render them available for this work, all we can do is to submit the following table: —

Characteristics of the tree, and general reputation of the fruit.

- Fruit sets with less air than most peaches
- Tree apt to midew
- One of the best peaches we have, not liable to the blight
- Fine fruit
- Good Tree not apt to mildew or gum
- Succeeds best on an apricot stock
- Requires much heat & fall seasons to attain full perfection
- Requires artificial heat, otherwise is only fit for baking or preserving
- A beautiful fruit, resembling in color the pomme d’apricot
- An excellent peach; large, yellow, and apricot-flavored
- Stone small, and deeply furrowed
- Excellent for forcing; or under cold glass
- An excellent fruit
4488. Selection of sorts. Abercrombie says, "Except the situation be completely favourable as to climate, aspect, and shelter, forbear to plant very early or extreme late fruit; the frost will almost inevitably cut off the former when blossoming and setting; and the latter will hardly ripen under the declining heat of autumn."

4489. The peaches proper for a small garden, according to Forsyth, are—

The early avant
Royal George
Anne

Early newington
Lothian
(\textit{H.})

Early purple chancellor

Nivette

4490. The peaches in the Dalkeith garden, and which ripen in the order in which they are placed as follows; those marked (\textit{H.}) being planted against hot-walls:

(W.) Early newington
(H.) Grimwoud’s royal George
(N.) Nivette

(H.) Bullogden

(H.) Miller’s mimonne

(W.) Smith’s early newington

(W.) White maghaden

The best varieties for fencing, according to Oldacre, are, the violet, native, mimonne, and Marlborough.

4491. Propagating to procure new sorts. The peach is raised from the stone; and this mode is pursued in America, even for procuring trees for common purposes. In Maryland and Virginia, Neil observes, “peach-trees are propagated from the stones without budding. Every peach-orchard contains of course numerous varieties. Among these, a few are always of superior quality; with the rest of the fruit pigs are fed.” The peaches (Nos. 38, 39) in the table, mentioned as produced by Knight, were thus originated: the parent trees were dwarfs planted in large pots; these being brought into a state of vigorous health, the pistils of the blossom of one sort were impregnated with the pollen of another; only three peaches were suffered to remain on each tree; and from sowing the stones of these, the Acton, scott, and spring grove, and other varieties, were produced: the male parent of the latter was the large French mimonne; and the female, the little red nutmeg; which choice is consistent with the general principle, that the most perfect and vigorous offspring will be obtained of plants, as of animals, when the male and female parent are not closely related to each other. (\textit{Nell.})

4492. Knight has some excellent observations on this subject in various papers published in the \textit{Hort. Trans.}; but especially in \textit{Observations on the Method of producing new and early Fruits, and on some Varieties of the Peach}. (vol.1.) In the latter paper he thus concludes, “I entertain little doubt that the peach-tree might, with proper care and caution, be made of any one of the climate of England and Ireland, as to succeed well as a standard in favorable situations. The peach does not, like many other species of fruit, much exercise the patience of the gardener, who raises it from the stone, and is not very difficult to transplant. It will not very likely fail in a single year; might not possibly produce fruit even at the end of a single year. In prosecuting such experiments, I would recommend the seedling peach-trees to be retained in pots, and buds from them only to be inserted in other trees; for their rapid and luxuriant growth is extremely troublesome on the wall, and pruning is done frequently in succession. The blossoms being formed during the summer, the flowers may be removed from the seedlings, as the French do, by cutting the branches near the stem, and the leaves as well as the shoots being cut as far to the ground as is possible to the sun, in order to promote the growth, and ripening of the wood."

4493. The most superior sorts of peach-trees, those which are firm and cleaves to the stone; and from amongst those, you should choose such as ripen early, and have a rich vinous juice. These stones should be planted in autumn, on a bed of light dry earth, about three inches deep and four inches asunder; and in the winter the beds should be covered to protect them from the frost, which, if permitted to enter, would injure them in two years. After removing the stones, these trees may be transplanted into nursery rows, three feet asunder, and one foot distant, plant from plant, in the rows, the surface, and watering during summer in very dry weather. After being two years in this nursery, the plants them where they remain to produce fruit. Plant them these standards till you see their fruit; cut off bruised roots, but give their tops no other pruning than cutting out decayed or very irregular branches.

4494. Propagation to perpetuate varieties. The peach is generally budded on damask plum-stocks, and some of the more delicate sorts on apricot-stocks, or old apricot-trees cut down, or on seedling peaches, almonds, or nectarines. Knight recommends growing almond-stocks for the finer kinds of nectarines, and apricots, as likely to prevent the mildew, and as being allied to the peach. He says, “almond-stocks should be raised and trained in the nursery, as they do not transplant well.” Dubrueil, after what you mentioned (437, 441.), recommends a plum-stock for a clayey soil, and the almond for such as are light, chalky, or sandy. The same opinion is held by the Montreuil gardeners. “Perform the budding in July or August, in the side of the stock, one bud in each, inserted near the bottom, for principal wall-trees; and the other so as to ride, for riders. The four, or five feet, for riders. This bud will shoot the following spring, and attain the length of three or four feet in the summer’s growth. After the budded trees have ripened the first year’s shoot, they may either be planted where they are to remain, or be trained in the nursery for two years or more. Whether this latter plan is to be followed in a bed, or state, it must be removed into the garden at a year old, or remain longer in the nursery, the first shoots from the budding must be headed down, either early in June the same year, to gain a season, or in the March following, to four, five, or six eyes, to produce lateral shoots, with one upright leader, to begin the formation of the head in a fan-like expansion; the second year’s shoots should also be shortened to a few buds, and headed down at half an inch, and those also of the third year in such degrees as may seem expedient.” At Montreuil, almond-stocks are used because the soil is dry; but Mozart prefers plum-stocks where the soil is strong and black. (\textit{Hort. Trans.})

4495. The French nurserymen graft both the peach and nectarine on the Mirabelle plum, a very small cherry-shaped fruit.

4496. Sold. A good soil for peach-trees, according to Abercrombie, “is composed of three parts mellow sand, one part drift sand, moderately enriched with vegetable mould, or the cooler dunghill, and at the same time a good and at the same time the bordering ground be composed dunghill and fertile mellow earth (new top-spt-loam, if attainable); if the ground be strong and heavy, so that the earth light or dunghill; if very gravelly, remove the grossest part, excavating to a proper depth; and in the same proportion apply a compost as above. Let the soil be made good to the depth of thirty inches for hardier sorts, and for very dry or sandy soil, three feet, or if any depth to breed. Bad cold ground, or an exhausted mould, is often the cause of the trees gumming.” Forsyth says, “Peaches require a lighter soil than pears and plums, and a light mellow loam is best.”

4497. Choice of plants. Abercrombie, Forsyth, Nicol, and most authors, agree in recommending the choice of trees, two, three, or four years trained. Forsyth says, “they should be procured in the latter end of October, or beginning of November, as soon as the leaf begins to fall.”

4498. Final planting. The peach is almost universally planted against walls in Britain; in some few warm situations they have been tried as dwarf standards, and Knight (\textit{Hort. Trans.}, vol. ii. p. 219.) thinks
they may be grown in cases as low as espaliers, covering with mats in spring to protect the blossom. In a very warm season there can be no doubt of the fruit of the hardy nectarine, and nectarine, and peach-tree bears would be less subject to the red spider. Early autumn planting is best on a dry soil. Spring planting may be successfully performed in February and March; the sooner, so as the weather be favorable, the better; that the trees may take root immediately before the dry winter season commences."

4498. Mode of bearing. "All the varieties of the peach and nectarine bear the fruit upon the young wood of a year old; the blossom-buds rising immediately from the eyes of the shoots. The same shoot seldom bears after the first year, except on some casual small spurs on the two years' wood, which is not to be counted upon. Hence, the trees are to be pruned as bearing entirely on the shoots of the preceding year; and a full supply of every year's shoots must be trained in for successional bearers the following season." (Abercrombie.) Du Petit Thouars denies the propriety of the distinction usually made of wood-buds and flowers in the peach-tree and staks, and that each leaf produces a bud at its base, which soon becomes triple, the two outer proving flower-buds, and the middle one a leaf or wood bud.

4499. The summer pruning. "In May and June, and occasionally in the succeeding months, is to regular blossom-bud, to avoid the shoots of the preceding year, and to prevent improper growths by disbudding. Pinch off fore-shortened buds or shoots; and pinch off or cut out ill placed, very weakly, spongy, and deformed shoots, and very strong luxuriant growths; retaining a plentiful supply of good lateral shoots in all parts of the tree; and leaving a leader to each branch. Let them mostly be trained in at full length all summer, about three inches asunder, for next year's bearers; and divest them of any lateral twigs, to prevent a thicket-like intricacy, and to promote a healthy fruitful growth in the shoots themselves. In the course of the summer regulation, if any partial vacancy occurs, or should a young tree under training want an additional shortening, some convenient placed strong shoot in June to a few eyes, to furnish a supply of laterals the same season."

4500. The winter pruning. "May be performed at the fall of the leaf, and thence, according to some professional writers, at any time in mild weather until spring. It should be completed in February, or even on the blossom. The branches are considered, the shoots forming a round, plump, and prominent, while the leaf and shoot buds are oblong and narrow. There is some advantage in pruning when the blossom-buds can be certainly known. Retain, in all parts of the tree, a competent supply of such regular-grown shoots of last year as are apparently fruitful in blossom-buds. Most branches should be shortened indiscriminately, but according to their strength and situation; the very strong shoots should be left longest, being topped about one fourth, or one third; shoots of middling vigor reduce one third or one half; and prune the very weak to two or three buds. Always cut a shoot lengthwise for a shoot, at a blossom-bud lies between a twin blossom-bud; cut half an inch above the bud. As many new shoots as will lay from three to six inches asunder may be deemed a competent supply for next year's bearers. Cut out quite close the redundant, irregular, and other improper shoots; remove or reduce some part of the former bearers of the two preceding years, cutting the wood away, and leave the last eligible younger branch or well placed shoot. Also take out all diseased and dead wood; retaining young, where necessary, to fill a vacuity."  

4501. A mode of pruning adapted to cold and late situations is recommended by Knight as calculated to obtain fruit-bearing shoots in the peach, and these he finds best calculated in such situations and late seasons, to generate well organised and vigorous blossoms. "Instead of taking off so large a portion of the young shoots, and training in a few only to a considerable length, as is usually done, and as I should myself do to a great extent, in the vicinity of London, and in every favorable situation, I preserve a large number of the young shoots, which are emitted in a proper direction in early spring by the yearling wood, shortening each where necessary, by pinching off the minute succulent points, generally to the length of one or two inches. Spurs which line close to the wall are thus made, upon which numerous blossom-buds form very early in the ensuing summer; and upon such, after the last most unfavorable season, I pinch off so high and so early, that the peaches, in the most favorable seasons, had usually produced only a few feeble blossoms. I observed as strong and vigorous blossoms in the present spring, as I have usually seen in the best seasons and situations; and I am quite confident that if the peach-tree around the manner in which it had been pruned in the manner above described, in the last season, an abundant and vigorous blossom would have appeared in the present spring. I do not, however, mean to recommend to the gardener to trust wholly, in any situation, for his crop of fruit to the spurs produced by the above-mentioned mode of pruning and training the peach-tree. In every warm and favorable situation I would advise him to train the larger part of his young wood, according to the ordinary method, and in cold and late situations only, to adopt, to a great extent, the mode of management above suggested. A mixture of both modes, in every situation, will be generally found to multiply the chances of the shoots to bear fruit, neither ought to be exclusively adopted, nor wholly rejected in any situation. The spurs must not be shortened in the winter or spring, till it can be ascertained what parts of them are provided with leaf-buds."

4502. Harrison, in a very elevated and cold situation, prunes and naps his peach and nectarine trees in December and January. Taking away two thirds of the young shoots, which are remnant in May and July, he leaves the lowest and weakest shoots for a succession in the year following, pinching off the leading and other shoots. J. S. Wortley, Esq. (Harrison's employer) says, "he can hardly do his gardener justice in describing his practice; for he never saw trees so beautifully trained, and upon such a sound plan as I have seen in his garden at Wortley. He feels it is the bearing fruit, to run to any length from the strong wood; for which reason, when the trees are pruned in autumn the bearing branches for the next year are shortened, taking care not to leave more fruiting-buds than the trees will come to perfection." (Hort. Trans. vol. ii. p. 11; Harrison's Tr. on Fr. Trees, ch. xvi.)

4503. Training. The peach is almost universally trained in the fan manner, though some allege that it bears better in rich soils when leading branches are trained nearly horizontally, and the bearing shoots trained upwards from those, thus combining horizontal and upright training. Hayward suggests the wavy-fan manner (fig. 450B), as likely to answer better than the common mode of fan-training.

4504. Mozart's mode of training peach-trees is as follows. He has one long shoot over the young tree above the graft, leaving four or five buds to produce as many branches. In July following, he cuts out close
to the main stem, all other branches than those absolutely needed for furnishing the tree. He trains regularly to the right and left; but the weaker branches receive less inclination, or are placed more upright, so that the branches in an irresponsible position may give them energy, and bring them to an equality of vigor with the stronger branches which are laid in horizontally. At the first regular forming or cutting in, about a year and a half after planting, the branches are reduced to two on each side; and at the next pruning, one branch is removed on each side, leaving the tree to be formed only of two primary branches. If the fruit form and the wood form are the same, the young branches do not from the first year's growth do not yield two sufficiently good leading branches, they are sought from the growth of the second year; the best branch of the former year is now, with this view, trained upright as a stem, and two fruitful branches are preserved by being tied in the sides so as to form shoots from it are allowed to remain. If the pruning is conducted on similar principles. It is a common rule to leave two secondary arms, of nearly equal strength, and about two feet apart, on each side. In trees managed in the way now described, the sap seems to be equally distributed; at least, the trees exhibit, upon the whole, a great equality of character, as a fruit and not of flowers. The fruit is allowed to set, or if the fruit form, it soon falls off, or at all events, is deficient in size and flavor. From four to eight flower-buds are left on each twig, according to its strength, and a fruit-bud at the extremity, when it can be there had, or between two flower-buds near the extremity. When this wood-bud expands into a shoot, these shoots are tied down and this remnant of the fruit is left alone. A more or less sufficient growth of or eight fruit-buds of the twig. Other wood-shoots, as they are called, which may appear below the fruit-buds, or nearer to the main branches, are cut down to one or two eyes. Mozard likewise resorts to dividing small trees. This practice is of great importance. 4505. Sieulle, gardener at Vauz Fraslin, adopts, for the first two years, a different mode of training and pruning from that of Mozard. The distinguishing characteristics of Sieulle's method are applicable to any very young peach-trees, in their first and second years. In the first year he does not at all cut or shorten the branches, but retains the natural distribution of the extremity. The branches are fixed to the wall or trellis, requiring no other treatment till the fall of the leaf. By leaving these mère branches in their full length, and only disbudding late in the autumn, the vigor of the young tree is greatly promoted. He trains these principal branches to a much wider angle than the Montreuil gardeners, perhaps something like 30° to 45°. At the first renewal of winter pruning in February or March, only four buds on each branch, and removing the rest neatly with a sharp knife. At Montreuil the mere branches are cut in or shortened in the first year, and disbudding is delayed till the leaves be developed in the second year. By disbudding at this season the young tree not only suffers an unnecessary check, but the consequence is that the buds left, instead of forming good shoots, develop themselves into numerous brindilles. Late in the autumn of the second year, Sieulle cuts in, to the extent of one third, the four lateral branches produced on each of his mere branches. In the following year, he disbuds the lateral branches to the extent of one half; and in the future management he practices winter disbudding greatly in place of pruning, a practice long ago strongly recommended by Nicol in his horticultural writings. By Sieulle's method, Du Petit Thouars remarks, the young tree is more quickly brought to fill his place on the sill; it is afterwards much more easily kept in regular order: many poorer flower-buds are allowed to unfold themselves, but the necessity of thinning the fruit is thus in a great measure superseded, and the peaches produced are larger and finer. (Hort. Tour, 479.) 4506. Thinning the fruit. In favorable seasons, the blossoms often set more fruit than they can support, or than have room to attain full growth; and if all were to remain, it would hurt the trees in their future bearing: therefore they should be timely thinned, when of the size of large peas or half-grown gooseberries. There should be a preparatory thinning before the time of flowering, and a final thinning afterwards, because most plants, especially such as have overborne themselves, drop many fruit at that crisis. Finish the thinning with great regularity, leaving those retained at proper distances, three, four, or five, on strong shoots, two or three on middling, and one or two on the weaker shoots; and never leaving more than one peach at the same eye. The fruit on weakly trees, thin more in proportion.” (Abercrombie.) 4507. Renovating old decaying trees. Head down, and renew the soil from an old upland pasture, and if the bottom of the border is moist, or if the roots have gone more than two feet, or and two a half feet downwards, pave the bottom, or otherwise render it dry and impervious to roots at the depth of twenty inches, or two feet from the surface. This plan will be found almost universally successful in restoring sufficient vigor to resist insects and diseases, and produce abundance of fruit. 4508. Protecting blossom. This may require to be done by some of the various modes already enumerated. (2926. to 2218.) Forsyth recommends old netting as the best covering. 4509. Harrison protects his trees from the frost, in the month of January, by branches of broom: these are previously steeped in soap-suds, mixed with one-third of urine, for forty-eight hours, in order to clear them from insects, and when dry, disposed thinly over the whole tree, letting them remain on only until the trees begin to break into leaf. At the time of the blooming and setting of the fruit he applies cold water in the following manner: viz. If upon visiting the trees, before the sun is up, in the morning, after a frosty night, he finds that there is any appearance of frost in the bloom or young fruit, he waters the bloom or young fruit thoroughly with cold water, from the garden-engine; and he affirms, that even

4517.

4511. Insects, diseases, &c. The leaves of the peach-tree are 491 very liable to the attacks of the acarus, its greatest enemy, and also to be devoured by the Chermes (fig. 491. a), Aphid (fig. 491. b), and even a much smaller insect, the Thrisus (fig. 492.),

which, in its natural size (c) is hardly perceptible with the naked eye. These are to be kept under by the usual means of watering over the leaves, and fumigation with tobacco-smoke. The honey-dew, mildew, gum, and canker, are chiefly to be kept under by regimen: dusting with sulphur has been found to destroy the mildew (Robertson, in Hort. Trans. v. 184.), but the only certain way of removing it is by a renewal of the soil, which will commonly be found old mould in use and too rich; and by abundance of air. J. Kirk. (Caled. Hort. Mem. iv. 159.) has tried renewing the soil of the nursery, and always found it an effectual remedy.

4510. Ripening peaches on leafless branches. Whenever the part of the bearing branch, which extends beyond the fruit, is without foliage, the fruit itself rarely acquires maturity, and never its proper flavor and excellence. This Knight conjectured to be owing to the want of the returning sap which would have been furnished by the leaves; and he proved it experimentally, by inarching a small branch immediately above the fruit. The fruit, in consequence, acquired the highest degree of maturity and perfection. (Hort. Trans. ii. 25.)

4512. Black spots or blotches are very apt to appear and spread on the young wood of the peach-tree, and are caused by aphis, or aphides, as they are called by the Roman writers, (Ovid.) the first time in the beginning of winter, 1811, I collected together a rich compost-heap (No. 1), consisting of one third light loam, one sixth strong clay, one twelfth lime, one sixth hot-bed dung, one sixth vegetable mould, and one twelfth pigeon-dung. At the same time, I collected another heap (No. 2), much less rich, consisting of one half light loam, one fourth strong clay, one eighthark from soucrens of ditch, one sixteenth lime, and one sixtenth hot-bed dung. These heaps I turned over occasionally, in order that they might be well mellowed by the frosts. About the middle of March, 1812, I planted the trees, and applied to the roots of each a covering of the heap of the compost No. 1. About the latter end of June, I examined the young trees all over, and observed that they had made nearly all of the same size; but I was no way disappointed when I found those I had planted with the rich mould, easily infested with black spots; while those planted with No. 2 remained whole and sound. There being only the few which were planted with No. 1, infested with the black spots. With my knife I cut the blemishes entirely out; and about the latter end of September I found the wounds completely whole. Early in the spring, 1813, I cleared off the rich mould entirely from their roots, and supplied the vacuum with No. 2; and at the end of last season I had the happiness to see not a single of them the utmost of the black spots. (Gibbs, Vis. of Bot. Gardens, ii. 29, 30.)

4513. The wasp (Vespula vulgaris), the large fly (Musca volumnaria), the ant (Formica vulgaris), and especially the earwig (Forficula auricularia), are enemies to the ripe peach. The three first may be excluded by nets, or enticed by honied bottles, and the last caught by the beetle-trap, reeds, or bean-stalks, laid in behind the leaves, and examined every morning.

4514. The Montreuil peach-growers wash water to off the aphides; pick off wrinkled, blotched, and mildewed leaves, and cut out canker and gum, and cover the wound with onguent de St. Fiacre, i.e. cow-dung, and oil of pimento, mixed in the same proportion. (Neill observ.)

4515. Gathering. Use the peach-gatherer, and gather one day or two before the fruit is to be used, and before it be dead-ripe, laying it on clean paper in a dry airy part of the fruit-room. See Chap. IV. Sec. III. and Chap. V. Sect. X.

4516. Forcing, and the use of hot-walls. The peach-tree forces well under glass, (See Chap. VII. Sect. III.) and its ripening may be accelerated in the open air, when planted against a hot-wall, by the application of gentle fires in cold moist weather, in August and September. This will ripen the fruit and wood, but attempts to accelerate the Lompeos ears in spring are very dangerous, as without the protection of glass they are almost certain of being cut off.

4517. The nectarine is distinguished from the peach by its smooth and rather firmer and more plump fruit. In other respects the general description of the peach equally applies to the nectarine, both, as before observed, being by the continental gardeners considered as one fruit. Forsyth says, "The fruit is called nectarine from nectar, the poetical drink of the gods." Some botanists, considering it as a distinct species, distinguish it by the trivial name of nucet-persica, from the similitude of the green fruit in smoothness, color, size, and form to the walnut (nux) covered with its outer green shell.

4518. The varieties are enumerated in the following table: —

Free Stones arranged in the order of their ripening.

Elruge; first cultivated at Hoxton, by Gurie, in 1680; (Hock. P. L. & For. 3.) mildewed and pale-yellow color; ripens in the middle of August; and is soft and melting.

Temple's (Long. P. t. 30. and For. 8.) medium size; pale-red and yellowish color; ripens in the middle of September; flavor rich and juicy.

Fairchild's early (For. 1.) small size; round figure; beautiful red color; ripens in the middle of August; flavor good.

Peterborough, Late Green, Vermouth (For. 10.)

Scarlet (For. 4.) small size; fine exterior; pale-red and yellowish color; ripens in the end of August.

Violet, Violet Hâtre (Hock. P. t. 15. For. 11.) medium size; purple and green color; delicious.

Murry (For. 7.) medium size; dingy red and pale green; ripens in the middle of September.

White, Flanders (Hock. P. t. 30. For. 28.) ripens in the beginning of September.
Late Newington (Lang. P. t. 29. For. 2.)
red and yellow color; ripens in the middle of Sept.; t. 1. & For. 143.
juice
Early Newington (Italian) (Lang. P. t. 29. For. 6.)
dark-red and pale-yellow color; ripens the beginning of
September; rich flavor

Red Roman, Brugmon Musqué (Duch.

n. 30. For. 63.) large size; dark-red color; ripens in September;
replete with rich juice
Golden (Lang. P. t. 30. For. 6.) medium size; soft red and yellow color; ripens in
the beginning of October; poignant rich flavor

Early Pavie (For. 57.)
Late Genoa (For. 57.)

Above medium size; ripens the end of August;
dark-red color; pulp very juicy;
and, according to Miller, one of the best flavored of
nectarines, or of any known fruit in the world
Roger's seedling. (For. 77.)

4519. Selection of sorts. Forsyth recommends for a small garden—
Fairchild's early | Elurge | Scarlet | Newington | Red Roman | Temple's.

(1.) Red Roman (H.) Dutilly's | (2.) Elurge (H.) Temple | Fairchild's (H.) Scarlet | (3.) Dutilly's | (4.) Elurge (H.) Temple

4521. Insects. "On account of the smoothness of the skin of the nectarine," Forsyth
says, "it suffers much more from the wood-louse (Oniscus asellus), ear-wigs, &c.,

than the peach; it will, therefore, be necessary to hang up a greater number of
bundles of bean-stalks about these than about any other fruit-trees. Wasps are also very destructive
to nectarines, and the trees are very liable to be infested with the red spider."
Culture. &c., This is in all respects the same as the peach.

Abricot, Fr. ; Abricosenbaum, Ger. ; and Albicocco, Ital.

4529. The apricot is a low tree, with broad roundish-pointed leaves, glandular, serrated, and the petiole commonly tinged with red. Linnaeus remarks, that the vernant leaves are convoluted, that is, not folded flat together, like those of the cherry, but rolling upwards, more or less. The leaves of many apricot-trees have a disposition to this at all times. The flowers are sessile, of a white color, tinged with dusky-red; fruit round, yellow within and without, firmer than plums and most peaches, enclosing a smooth compressed stone, like that of the plum. The flowers appear in April, on the shoots of the preceding year, and on spurs of two or more years' growth, and the fruit ripens in September. From its trivial name, it is generally supposed to have originated in Armenia, but Regnier and Sickler assign it a parallel between the Niger and the Atlas; and Pallas states it to be a native of the whole of the Caucasus, the mountains there, to the top, being covered with it. Thunberg describes it as a very large, spreading, branchy tree in Japan. Grossier says that it covers the barren mountains to the west of Pekin, that the Chinese have a great many varieties of the tree, double-blossoming, which they plant on little mounts for ornament, and dwarfs in pots for their apartments. It appears from Turner's Herbal, that the apricot was cultivated here in 1562; and in Hakluyt's Remembrancer, 1582, it is affirmed, that the apricot was procured out of Italy by Wolfe, a French priest, gardener to Henry VIII. The fruit seems to have been known in Italy in the time of Dioscorides, under the name of Præcoxia, probably, as Regnier supposes from the Arabic, Bercoch; whence the Tuscan, Baccoce or Albicocco; and the English, Apricock; or, as Professor Martyn observes, a tree, when first introduced, might have been called a præcox, or early fruit; and gardeners taking the article a for the first syllable of the word, might easily have corrupted it to apricocks. The orthography seems to have been finally changed to apricot about the end of the last century; as Justice, in 1764, writes apricock; and Kyle, of Moredin in 1782, apricot.

4593. Use. The fruit is used in a raw state at the dessert, and is esteemed next to the peach; it is also made into marmalades, jellies, and preserved. Grossier says, that lozenges are made by the Chinese, from the clarified juice, which, dissolved in water, yield a cool refreshing beverage: oil may be extracted from the fruit, and the young shoots yield a fine golden cinnamon-color to wool.

5924. Varieties. Parkinson, in 1629, enumerates six; Rea, 1720, seven; the Luxem-
burg catalogue in 1800, fifteen; and the British catalogues enumerate about the same number.

Masculine, Early Red Masculine; an old variety, mentioned by Parkinson in
Hesperides, B. 4. p. 105.; small size; roundish form; greenish-red color; ripens in the end of July; the pulp tender, with a tart taste; the tree a good bearer, and the fruit esteemed for its earliness, and tart taste.
Orange; mentioned by Rea in 1702 (Lang. P. t. 15. and For. 4.) large size; round form; deep-yellow color; ripens in the middle of August; the pulp not very juicy.
Turkey; mentioned by Rea in 1702 (Lang. P. t. 15. and For. 4.) large size; globular form; very deep yellow color; ripens in the end of August; the pulp firm and dry.

Breda; brought from Africa to Brygla, and thence to England in 1702 (For. 65.) large size; round form; deep-yellow color; ripens in the end of August; the pulp soft and juicy; the tree a great bearer; an excellent fruit, especially if grown on standards, to which this sort is particularly adapted.

Brussels; mentioned by Rea as brought from Brussels in 1702 (Pom. Aud. T. 27. and For. 7.) medium size; inclining to an oval form; red, with dark spots, and greenish-yellow color; ripens in the end of August; the pulp not liable to be mealy, or doughy; brick flavor; the tree a great bearer; and held in great esteem on account.
of its bearing so well in standards, or large dwarf.

Moore Park; Anson's, Temple's, Dunmore's, Breda, and Peach Apricot; brought from the Netherlands by Sir Thos. Moore, say in 1700 (Hook. Fl. t. 9. and For. p. 4.); ripens in the end of August; fine fruit; according to Nicol, preferable to all other apricots.

Peach Apricot; Apricot of Nury; brought from Paris by the Duke of Northumberland, in 1767 (Duh. 4525. Choice of sorts. Those grown in the Dalkeith gardens are—

Moor Park | Breda, early | Masculine, early | Brussels, early | Orange, early.

4520. Propagation. New varieties are procured from the seed as in the peach, and approved sorts are perpetuated by budding, generally on muscle or plum stocks. The Brussels and Breda, when intended for standards, are budded on the St. Julian plum, which produces a strong clean stem; but for the rest, any stock will do, provided it be free and thriving. Knight (Hort. Trans. vol. ii. p. 19.) recommends budding the Moor Park on an apricot-stock, which he has found prevents the trees of this sort from becoming diseased and debilitated, which they generally do on plum-stocks. Budding apricots is generally performed early in the season, from the middle of June to the end of July. For dwarfs, the bud is inserted six or eight inches from the ground; and the sorts are sometimes twice budded, or one variety budded on another, which is said to keep the trees in a more dwarf state. For riders or standards, they are budded on plum-stocks four or five feet high. Miller prefers half standards, budded about three or four feet from the ground; the trees so produced, being less liable to suffer from high winds.

4521. Choice of the plants. Abercrombie prefers trees of two or three years' growth from the bud, and fit for immediate bearing. Forsyth makes choice of those plants which have the strongest and cleanest stems; and if he can such as have been headed down, of two or three years' growth, as they will bear and fill the walls much sooner than those which have not been so treated. He says, "make choice of trees with one stem; or, if they have two, one of them should be cut off; for by planting those with two stems, the middle of the tree is left naked, and of course, one third of the wall remains uncovered." 4528. Season of planting. Abercrombie says, the best season is from the fall of the leaf until February or March. Forsyth says, the best time is in August, when the leaf begins to fall.

4529. Final planting. The Breda and Brussels are occasionally planted as standards or espaliers in warm situations; and in these states, in fine seasons, produce more highly flavored fruit than on walls. The other varieties are generally planted on walls, which, Miller and Forsyth say, should have an east or west aspect; for, if they are planted full south, the great heat causes them to be mealy before they are eatable. The borders should not be less than six or eight feet wide, and two or two and a half feet deep. The soil a light rich loam, perfectly dry below. Forsyth says, "the borders may be three feet deep." "Standard apricots," Abercrombie observes, "do not come into bearing under a considerable number of years, sometimes ten or twelve; but then the fruit, in a congenial situation, is abundant and of the finest flavor. So, when the prevailing fault of a particular sort is mealliness, and yet it cannot be expected to ripen on even a dwarf standard, the medium course of training the plant to a trellis almost touching a south wall, will improve the flavor."

4530. Mode of training. The fan method is very generally adopted with this tree: Forsyth prefers the horizontal manner, and Harrison also trains horizontally, but "so as to let the branches have an elevation to their extremities of 20 degrees, varied, however, according to the luxuriancy or weakness of the tree." With young trees he proceeds to fill the wall by heading down, twice a year, in the same manner as with the apple and pear. The result produces a tree (fig. 493.) not essentially different from Forsyth's engraving. (Tr. on Fr. Tr. chap. xxiv.)

4531. Mode of bearing. The varieties of the apricot, in general, bear chiefly upon the young shoots of last year, and casually upon small spurs rising on the two or three
year-old fruit-branches. The Moor Park bears chiefly on the last year’s shoots, and on close spurs formed on the two-year-old wood. The bearing shoots emit the blossom-buds immediately from the eyes along the sides; and the buds have a round and swelling appearance.

4539. Pruning wall-trees. The general culture of the wall-apricots comprehends a summer and winter course of regulation by pruning and training.

4540. Summer pruning. Begin the summer pruning in May or early in June, and continue it occasionally in July, August, &c. This pruning is principally to regulate the young shoots, of the same year. In the first place, take off all the new growth, and others that are ill placed or irregular, or too luxuriant in growth; taking care to retain a competent supply of choice, well placed, moderately growing side shoots, with a good leader to each mother branch. Continue these mostly at their full length all summer, regularly trained in close to the wall, to procure a sufficiency to choose from in the general winter pruning, for new bearers next year. If the summer regulation commence early, while the shoots are quite young, and, as it were, herbaceous, one, two, three, or four inches long, those improper to retain may be detached with the finger and thumb; but when of firmer growth, they must be removed with the knife. Any very strong shoot may be retained in this part of the wall, which will cause it to produce several laterals the same year of more moderate growth, eligible for training in to supply the vacancy.

4541. Thinning the fruit. Sometimes the fruit are much too numerous, often growing in clusters; in which case, thin them in May and the beginning of June, in their young green state; leaving the most promising fruit singly, at three or four inches’ distance, or from about two to six on the respective shoots, according to their strength. The apricots so thinned off, and the first principal green fruit, are esteemed very fine for tarts.

4542. Winter pruning. This may be performed either at the fall of the leaf, or in mild intervals from that time until the beginning of March. When it is deferred until the buds begin to swell, the promising shoots can be better distinguished. It comprehends a general regulation both of the last year’s shoots and the older branches. All the general supplies of the most regular-placed young shoots must be very where retained, for successional bearers the ensuing year. Cut out some of the most naked part of the two last year’s bearers, and naked old branches not furnished with competent supplies of young wood, or with fruit-sprays, either to their origin, or to some well directed lateral, as most expedient, to make room for the new fruit shoots. The reading of the principal shoots, which will cut off one fourth or less of their length; from weak shoots take away a third, and sometimes half. This shortening will conduce to the production of a competency of lateral shoots the ensuing summer, from the lower and middle-placed eyes; whereas, without it, the new shoots would proceed mostly from the top, and lessen the fruit under part of the mother branches naked, and the lower and middle parts of the tree unfurnished with proper supplies of bearing wood. Never prune below all the blossom-buds, except to provide wood, in which case cut nearer to the origin of the branch. As in these trees, small fruit-sprays, an inch or two long, often appear on some of the two or three years’ branches furnished with blossom-buds; these spurs should generally be short and cut off close to the wall, and left to produce fruit. As, when the young shoots ripen in the summer, they will scatter the blossom buds, and thereby lessen the fruit, and the wood furnished with the blossom buds on the next years. Pruning for the purpose of bearing in 1854, without the least injury is allowed. Beyond this, any pruning exceedingly increases the fruit, and diminishes the wood, and generally makes the tree too weak to bear fruit. There is a practice of grafting thick clusters of apricots on thin trees, which is apt to form on aged trees, and to be thinned off in each tree, pole it, nail it, laying in the branches and shoots from three to six inches’ distance, straight and close to the wall.

4543. Pruning espaliers. As directed for wall-trees.

4544. Pruning standards. Half standards will require only occasional pruning to regulate any branches which are too numerous, too extended, or crossed; and to remove any casually unfruitful parts and dead wood. At the same time, the regular branches, forming the head of the tree, should not be generally shortened, but permitted to advance in free growth. (Abercrombie.)

4545. Renovating old decaying trees. Forsyth has had the greatest success in this department of fruit-tree culture, by cutting down to within a foot or eighteen inches, or more, of the ground, and then renewing the soil of the border. He says “it has been the general practice to train apricot-trees on walls in the fan form, which occasions the sap to rise too freely to the top, leaving the lower part almost naked; so that scarcely one quarter of the wall is covered with bearing wood.” His remedy for this evil is to “cut down the whole of the tree, as near to the place where it was budded as possible; remembering always to cut it to an eye or joint. If there should be any young shoots on the lower part of the tree, it will be proper to leave them, training them horizontally, which will check the flow of the sap, and thereby render them much more fruitful. (Tr. on Fr. Tr. ch. 1.)” Harrison says, “Apricots are very susceptible of injury from pruning away any strong branches.” Instead of heading down old peach, apricot, or plum, or even cherry trees, he generally prefers rooting them out and planting young ones.

4546. Gathering. The fruit is apt to become mealy, if left on the tree till over ripe; it should be gathered with the peach-gatherer while moderately firm.

4547. Insects, diseases, &c. As the fruit ripens early, it is very liable to be attacked by wasps and large flies, which should be kept off by a net, stretched a foot or more apart from the wall or trellis. The other insects, and the diseases of this tree, are the same as in the peach-tree; but it is not nearly so obnoxious to their attacks, probably owing to the comparatively hard nature of its bark and wood, and coriaceous leaves.

4548. The apricot does not force well; but a few are sometimes tried in pots, and placed in the greenhouse. See Chap. VII. Sect. III. 

4549. The common or sweet almond is the A. communis, L.; and the bitter almond is the A. amara, L. (Blackw. t. 195.) Both will grow to the height of twenty feet, with spreading branches. The leaves resemble those of the peach, but the lower serratures are
glandular, which has given rise to the conjecture that glandular-leaved peaches have sprung more immediately from the almond than such as are without glands, as is generally the case with nectarines. The flowers vary in their color from the fine blush of the apple-blossom to a snowy whiteness. The chief obvious distinction is in the fruit, which is flatter, with a coriaceous covering, instead of the rich pulp of the peach and nectarine, opening spontaneously when the kernel is ripe. It is a native of Barbary, China, and most eastern countries. The tuberes of Pliny, Knight considers as swollen almonds, and the same with the amandier pêcher, or almond-peach, described by Du Hamel: having raised a similar variety from dusting the stigma of the almond with the pollen of the peach, which produced a tolerably good fruit. ( Hort. Trans. iii. 4.) The almond is mentioned by Turner in 1548, and, though scarcely worth cultivating in England as a fruit-tree for profit, yet it is a very satisfactory thing to produce almonds of one’s own growing at the dessert. The tree forms an important article in the general culture of many parts of France, Italy, and Spain. In a forward spring the blossoms often appear in February, but in this case frost generally destroys them, and they bear little or no fruit; whereas, when the trees do not flower till March, they seldom fail to produce fruit in abundance.

4543. Use. The kernel of the stone is the only part used, which is tender, and of a fine flavor. The sweet almond and other varieties are brought to the dessert in a green in an imperfectly ripe, and also in a ripe or dried state. They are much used in cookery, confectionary, perfumery, and medicine. “Sweet almonds used in food,” Professor Martyn observes, “are difficult of digestion; and afford very little nourishment, unless extremely well comminuted. As medicine, they blunt Jeremiah; and sometimes give instant relief in the heartburn.”

4544. Varieties and species in cultivation. Miller enumerates three species, Du Hamel seven; the number of sorts at present grown in the nurseries are as follows:­

| Sweet, Common Sweet (Duh. n. 5. and For. 2); large size; bitter almonds sometimes found on the same tree. | Peach Almond, Amandier Pécher (Duh. n. 2. t. 4. and Hort. Trans, 5 t. 1.); produces some fruits; pulpy and of tolerable good flavor; and others mere almonds; some partake of both natures. |
| Bitter, Common Bitter (Proc. Frang. i. 67. and For. 2); large size; sweet almonds sometimes found on the same tree. | Pistachio, Amande Pistache (Miller, 4.); very small size. |
| Dwarf (Duh. n. 8. and For. 6.). | |

4545. Selection of sorts. The tender-shelled is in the greatest esteem; and next, the sweet and Jordan.

4546. Propagation. The almond is propagated, like the peach, by seed, for varieties, or for stocks; and by budding on its own or on plum stocks, for continuing varieties. Plum-stocks are preferred for strong moist soils, and peach or almond stocks for dry situations.

4547. Final planting. It is generally planted as standards in shrubberies, and these will sometimes in good seasons ripen their fruit; but when fruit is the object, it should be trained against a west or east wall, like the peach.

4548. Mode of bearing and pruning. The almond-tree bears chiefly on the young wood of the previous year, like the apricot and peach; and in part upon small spurs on the two-year-old, three-year-old, and older branches: it is therefore pruned like these trees.

4549. Gathering and preserving the crop. A part may be gathered when nearly ripe daily for some weeks before gathering the whole crop. This operation generally fails to be performed in September, when a part may be laid in the fruit-room, and a part thoroughly dried and bedded in sand in the fruit-cell, for keeping through the winter.

4550. The plum-tree rises fifteen feet in height, branching into a moderately spreading head; the leaves are oval, serrated, and on short pedicles. Petals white, drupe an oblong spheric, shell long, ovate, and compressed. The natural color of the plum is generally considered to be black; but the varieties in cultivation are of yellow, red, blue, and green colors, and of different forms and flavors. It is a native, or naturalised in Britain, being frequently found in hedges; but its original country is supposed to be Asia, in Europe; and, according to Pliny, it was brought from Syria into Greece; and thence into Italy.

4551. Use. The best varieties are esteemed a delicious dessert fruit; and the others are used in pies, tarts, conserves, and sweetmeats. A wholesome wine is also occasionally made from them, with or without other fruits and ingredients. “Plums,” Professor Martyn observes, “when sufficiently ripe, and taken in moderate quantity, are not unwholesome; but in an immature state, they are more liable to produce colicky pains, diarrhoea, or cholera, than any other fruit of this class. Considered medicinally, they are emollient, cooling, and laxative, especially the French prunes, which are peculiarly useful in constive habits. The wood of the plum is used in turnery, cabinet work, and in making musical instruments.”

4552. Varieties. Tusser enumerates ten; Parkinson, sixty; Miller, only thirty sorts. In the Luxembourg catalogue are sixty-eight; nearly a hundred names are to be found in the catalogues of our nursemens, of which those in the following table are deemed the best.
A DESCRIPTIVE CATALOGUE OF PLUMS, commonly propagated in British Nurseries, arranged as Dessert and Kitchen Fruit.

4555. Propagation. Most of the varieties are propagated by grafting or budding on the muscle, St. Julian, Bourbonnais, or any free-growing, raised, from the choice stocks for a permanent plantation. The common baking plums, as the damson, bil核酸, wentworth, &c. are generally propagated by suckers, without being either budded or grafted. Plum-grafting is performed in July or March; budding in July or August. Miller prefers budding, because plums are very apt to form large warts on the scion; a shade on the scion, resembling a May-duke when half ripe, is planted to form hedges about Ghent, and used by the Flemish nurserymen, as stocks for both nectarines and peaches. (Neill, in Hort. Tour.)

4556. New varieties are procured by propagating from seeds on the general principles already stated. Knight (Hort. Trans. iii. 214), in an attempt to combine the bulk of the yellow magnum bominum with the richness and flavor of the green gage, produced a fruit which partook of both parents, but which has not yet given to the public; but a good variety of the Orleons plum. (Hort. Trans. iii. 392).

4557. Soil. Plums, according to Miller, should have a middling soil, neither too wet and heavy, nor over light and dry, in either of which extremes they seldom do well. Abercrombie recommends any mel-

4558. Site. The plum is cultivated like other indigenous fruit-trees: the hardier sorts, as standards; and the finer varieties against walls. It is sometimes forced; but the blossom, like that of the cherry, is difficult to set, and when the fruit is not well adapted for forcing. The finer varieties are almost always planted against walls, which, Miller says, should have an east or south-east aspect, which is more
to these fruits than a full south aspect, on which they are subject to shrivel and be very dry; and many sorts will be extremely mealy, if exposed too much to the heat of the sun; but most sorts will ripen extremely well on exposed walls, planted along fences or hedges, in which method some of the ordinary sorts will bear very well; but then the fruit will not be near so fair as those produced on espaliers, and will be more in danger of being bruised or blown down by strong winds. Abercrombie says, " some have choice sorts against south walls for earlier and superior fruit; others on east and west walls, and espaliers, to ripen in succession, with full and half standards in the orchard." Abercrombie directs full and half standards to be planted at forty, thirty, twenty-five, and twenty feet distance; dwarfs generally twenty feet apart, and wall-trees or espaliers fifteen, twenty, or twenty-five feet from stem to stem. Forsyth says, " Mirrors and cherries thrive best themselves; and he prefers a wall for each, placing plums on walls ten feet high, eight yards apart; and at seven yards' distance on twelve-feet walls.

4562. Mode of bearing. " All the sorts produce their fruit on small natural spurs, rising at the ends and along the sides of the bearing shoots of one, two, or three years growth. In most sorts, new fruit-branches are two years old before the spurs bear. The same branches and spurs continue fruitful in proportion to the time which they take to come into bearing."

4563. Mode of training. Forsyth and Harrison decidedly prefer the horizontal manner,

4564. Pruning. After the formation of the head is begun, it takes from two to six years before the differ-
te manners come into bearing. Miller trains horizontally, and is against shortening the branches of plum-trees, since the more these trees are pruned, the more luxuriant they grow, until the strength of the limbs is exhausted, and then they gum and spoil; therefore the safest method to manage these trees is to lay in their shoots horizontally, as they are produced at equal distances, in proportion to the length of their leaves, pinching off the points of young shoots where lateral branches are desired, and displacing more-right and more north such as the fruit. With the most carefully going over these trees in the growing season, there will be but little work to do to them in the winter.

4565. Abercrombie agrees with Miller in not shortening fruitful branches. Standards, he says, must be allowed to " expand in free growth, occasionally pruning long ramblers, and crossing-placed or other irregular branches. Thin crowded parts, cut away worn out busers, also decayed and cankered wood.

4566. Forsyth says, " Never cut the stems of young plum-trees when first planted, but leave them till the buds begin to break; then you may head them down to five or more eyes, always observing to leave an odd eye for the leading shoot; remember to cut sloping towards the wall, and as near to an eye as possible; the shoots then fill the spaces, and the fruit is luxuriant; but if the shoots are too luxuriant, you may pinch the tops off with your finger and thumb, about the beginning of June, in the first year after planting; by doing which you will obtain plenty of wood to fill the bottom of the shoots. A great deal depends on the first and second year's management of your trees."

4567. Removing decaying trees. Proceed as directed for the peach; but observe that the plum-tree, when cut down, is very apt to run to wood, therefore the new soil must neither be very rich, nor laid on in a very deep stratum.

4568. Protecting blossom. This is sometimes done with the tenderer sorts, in the same way as for peaches and apricots.
4569. **Taking the crop.** The different sorts of the plum ripen in succession for about three months in summer and autumn. Some early sorts begin to ripen in July; the main varieties reach full maturity in August and September; late sorts continue ripening till the end of October or beginning of November. Each kind should be brought to table presently after being gathered, as they will not keep long in a natural state.

4570. **Forcing the plum.** Plums may be forced in pots, or otherwise, like other fruit trees. Grange and Alton have forced them both ways; the latter thus describes his practice. "The sorts generally preferred for forcing are the following, Prunus-de-Tours, green gage, blue gage, white peregrin, Orleans, New Orleans, and Morocco. Some others have been tried, as La Royale, sienneux, and blue peregrin, but are found objectionable, the two first producing fruit void of flavor, and the latter has a tendency to crack the gum."

4571. **When an early crop is desired,** plums are best forced in large pots or tubs, as this method admits of their removal at pleasure into different degrees of temperature, as occasion may require; but for a general crop to ripen by the end of May, or beginning of June, it is preferable to have the trees planted in the forcing-house, and if they are intended to be forced in the first year, proper trees for the purpose furnished with well branching wood, should be selected and planted early in the autumn, that they may establish themselves before the winter sets in. The soil to be preferred is a moderately rich loam, without mixture of manure.

4572. For a crop to ripen in the second week in May, the house must be covered in early January, commencing with a temperature of 45° Fahrenheit, for the first fortnight, after which the heat may be gradually raised to 50°, at which it may continue until the flowers make their appearance; during this time frequent changes of air must be admitted, to strengthen the bloom, and the crop will be rendered more certain by keeping the trees in blossom as long as possible, by light shading, where necessary; and when the petals begin to fall, gentle dews may be raised from the surface of the mould. As the fruit forms, the thermometer should be raised to 55°; this must be done gradually, as the consequence of a rapid rise may be a casting of the fruit. During the process of storing great care must be taken against the sudden variations of the temperature, water very sparingly used, and every check by fumigation be given to the various insects which will be particularly active at this period. When the fruit is safely stoned, a moderate dressing of rotten manure may be spread on the surface of the mould; the heat increased to 60°, and a more liberal supply of water given. After the fruit has attained a full size, and approaches maturity, air may be freely admitted, and water should be given in less quantities, and finally discontinued, a few days before gathering.

4573. **Insects, diseases, &c.** See Peach. The gum and canker are the most common diseases, and, as in almost every other case, the acarus is the most noxious insect. As a remedy for the former, Abercrombie directs to head down. The insects are destroyed by the common means. The gages, or reine Claudes, when nearly ripe, are very apt to be eaten by wasps.

**Subsect. 6. Cherry. — Prunus Cerasus, L.** (Eng. Bot. 706.) *Icône Di-Pontag, L.* and *Rosaccu, J. Cersier, Fr.* ; *Kirschbaum, Ger.* ; and *Cirigio, Ital.*

4574. **The cherry** is a middle-sized tree, with ash-colored, shining, roundish branches, ovate serrated leaves, and white flowers, produced in nodding umbels, and succeeded by a red drupe, with an acid pulp. The leaf and flowering buds are distinct, the former terminating, the latter produced from the sides of the two or more years' branches. The cultivated cherry was brought to Italy by the Roman general Lucullus, in 73 A. C. from a town in Pontus in Asia, called Cerasus, whence its specific name, and was introduced to Britain 120 years afterwards. Many suppose that the cherries introduced by the Romans into Britain were lost, and that they were re-introduced in the time of Henry VIII. by Richard Haines, the fruiterer to that monarch. But though we have no proof that cherries were in England at the time of the Norman conquest, or for some centuries after it; yet Worton has proved, by a quotation from Lidgate, a poet who wrote about or before 1415, that the hawkers in London were wont to expose cherries for sale, in the same manner as is now done early in the season. The tree is now very generally cultivated both as a wall and standard fruit, and has been forced for upwards of two centuries.

4575. **Use.** It is a refreshing summer fruit, highly grateful at the dessert, and affording pies, tarts, and other useful and elegant preparations in cookery and confectionary. Steeping cherries in brandy qualifies and improves its strength and flavor; a fine wine is made from the juice, and a spirit distilled from the fermented pulp. The gum which exudes from the tree is equal to gum arabic; and Hasselquist relates that more than one hundred men, during a siege, were kept alive for nearly two months, without any other sustenance than a little of this gum taken sometimes into the mouth, and suffered gradually to dissolve. Cherry-wood is hard and tough, and is used by the turner, flute-maker, and cabinet-maker.

4576. **Varieties.** The Romans had eight kinds; red, black, tender-fleshed, hard-fleshed, small bitter-flavored, and a dwarf sort. Tusser, in 1573, mentions cherries red and black. Parkinson mentions thirty-four sorts, Ray twenty-four, and Miller has eighteen sorts, to which he says others are continually adding, differing little from those he has described. The catalogue of the Luxemburg garden contains forty-two sorts, and those of our nurseries exceed that number of names. As usual, we have inserted only those sorts of which we could obtain some authenticated descriptive particulars. The French divide their cherries into griottes or tender-fleshed, bigarœau or hard-fleshed, and guignes, geans or small fruits.

</table>
4578. **Selection of sorts.** Forsyth recommends, for a small garden—

- *The may-duke*
- *The mororlo*
- *The Harrisons heart*
- *The Turkey heart*
- *The Remington duke cherry.*

4579. **Those in the Dalkeith garden are—**

- *The early may-duke, two sorts*
- *The black heart*
- *The white heart*
- *The amber heart*
- *The mororlo; all against walls.*

4580. **Miller says, the best sorts for an orchard are the common red or Kentish, the duke, and the lukewood; all of which are plentiful bearers.**

4581. **Propagation.** Varieties of the cherry are continued by grafting or budding on stocks of the black or wild red cherries, which are strong shooters, and of a longer duration than any of the garden kinds. The chierry-trees of the hardy kinds are budded in February, and those of the more tender kinds in March, and proceeded as the same effect on the cherry, that the paradise-stock has on the apple, that of dwarfing the tree and rendering it more prolific. Some graft on the mororlo for the same purpose, but the most effectual dwarfin- stock is the mahaleb. Dubreuil of Rouen recommends the wild cherry for clayey and light soils, and the paradise樱桃 for sandy soils, which are those of the cultivated cherry are commonly, but improperly, substituted for those of the wild sort, as being more easily procured. New varieties are procured by propagating from seed, and some valuable fruits will be found in the table, so insae by Knight. The cherry, this gentleman observes (Hort. Trans. ii. 133.), "sports more extensively in variety, when propagated from seeds, than any other fruit which I have hitherto subjected to experiment: and this species of fruit is therefore probably capable of acquiring a higher state of perfection than it has ever yet attained. Now varieties are also much wanted; for the trees of the best kinds are every where in a state of decay in the cherry orchards; and I am quite confident, that neither healthy nor productive trees will ever be obtained from grafts or buds of the old and expendued varieties of this or any other species of fruit-tree." Cherry-stones, whether for stocks or new varieties, are sown in light sandy earth in autumn; or are preserved in sand till spring, and then sowed. They will come up the same season if they should not be exposed to the second autumn's heat and raining. They may be sowed in drills, two or three inches deep, in rows three feet apart, and the plants one foot asunder in the row. The succeeding summer they will be fit to bud, if intended for dwarfs; but if for standards, they will require to stand one or more seasons, generally till four years old. They should be budded or grafted near six feet from the ground; the usual way is to plant in November, and graft them the following spring.

4582. **Soil.** The cherry delights in a dry sandy soil and elevated situation; but some sorts, as the may- duke, will thrive in all soils and aspects, and all the varieties may be planted in any common mellow garden or on any light soil. Plants in a deep loam incumbent on rock. Miller says, the soil which cherries thrive best in, is a fresh hazel loam; if it be a dry gravel, they will not live many years, and will be perpetually blighted in the spring.

4583. **Site.** To obtain fruit early, some sorts, as the may-duke, are planted against walls; but all the varieties will do well as dwarfs or espaliers in general situations, and most of them as standards. The may-duke, Nicol observations, does well as a standard; but against a south wall the fruit becomes considerably larger, and contrary to what happens in other fruits, it seems to acquire a higher flavor. The mororlo is much improved in flavor when planted against a wall of good aspect. Abercrombie says, "Allot to the finest of the early kinds south walls for fruit in May and June; others against west and east walls, for supplies in succession; and some on north walls for the latest ripener, particularly the mororlo, which, so situated, will continue in perfection till September and October: but it is also proper to plant some trees of this sort on south walls, to have the fruit ripen earlier, with improved flavor."  

4584. **Planting.** "Plant full standards from twenty to thirty feet apart; small standards, fifteen, eighteen, or twenty feet. The proper season for planting is from the middle or end of October, or any time in November or December, if open weather, till February or March." Miller says, never plant standards. Better to ride cherry-trees over other fruits; for there is no sort of fruit that will prosper well under the drip of cherries. He allows forty feet square for standards in orchards for the same reason.

4585. **Mode of bearing.** "Cherry-trees in general produce the fruit upon small spurs or studs, from half an inch to two inches in length, which proceed from the sides and ends of the two-year, three-year, and older branches; and as new spurs continue shooting from the extremities of the tree, it is a maxim in pruning both standards and wall-trees, not to shorten the bearing branches, nor there is room for their regular extension. The mororlo is in some degree an exception."

4586. **Mode of training.** Forsyth and Harrison train in the horizontal manner, and practise shortening the leading shoots as in the plum, apple, &c. For the mororlo Harrison adopts the horizontal or half-fan method, "the horizontal method when the tree grows very vigorous, and the half-fan method when weaker." (Tr. on Fr. Tr. ch. xxiii.)

4587. **Pruning cherry-trees in general.**—Standards. Give only occasional pruning, to reform or remove any casual irregularity from cross-placed or very crowded branches; and take away all canker and decayed wood.

4588. **Wall-trees.** "A summer planting, to commence in May or June, is necessary to regulate the shoots of the tree. Disbudd the superfluous and fore-right shoots; or if they have been suffered to spring, pinch or cut them off, with such as are disorderly. Retain a competent supply of some of the best well-placed side and terminal shoots, to remain for selection at the winter pruning. Nall or lay in the reserve close to the wall, at their full length, and so train them all winter. The summer pruning may be attended to, to a less degree, during the winter. We may reject with the greatest facility both the old and young wood. Carefully preserve the sound productive branches and bearers in their full expansion; and reduce or remove such only as are irregular in growth, too crowded, unduly long, or dead, and all extraneous, or extending from the principal, primary, or good lateral, shoot or fruit-bud. According to the time the bearers have already lasted, look to some promising shoots, for successors to those which may now first wear out. To fill immediate vacancies, retain select shoots of last year, and the year before, with uniformly a leader to the advancing branch where there is room, and without causing any injury to the productive shoots near the spine. The objects of pruning are, to remove the bearers between the main branches. Some cut superfluous fruit-shoots clean away; others leave a sprinkling of short stubs, cut very short if fore-right. The new laterals and terminals are to be trained just in full length, as far as room will permit. They will come into bearing the first and second year. In propriety and convenience it is best to remove the spurs as they ripen, and not when they are green; wall-trees any old spurs project considerably, and assume a rugged disorderly appearance; cut such clean cut smoothly."

4589. **Pruning the mororlo.** "The mororlo cherry bears principally on the shoots of last year, the fruit proceeding immediately from the eyes of the shoots; and bears but casually, and in a small degree on close spurs formed on the two-year-old wood, and scarcely ever on wood of the third year. Therefore, both in the summer and winter pruning, leave a supply of last year's shoots, on all the branches, from the origin.
to the extremity of the tree, for next year's bearers; cutting out past bearers to make room. It is plain that the morelo ought to have no stubs left with a view to spurs, and all fore-right shoots ought to be disbudded while young. To leave a convenient space for young wood, train the present bearers six inches apart; lay in between each of these one young shoot for bearing next year, which will make the promi-

ness of distance three inches."

4590. Underwood (Caled. Mem. i. 427.) has often observed, when the branches of cherry-trees are laid in too near to one another, or are crossed by branches of the same kind, or by plum-tree branches, as is sometimes the case, that although there be abundance of blossom, yet there is no crop, even in good seasons. On examining the blossom, produced on such crowded shoots, he found, that in fifty flowers, there were not above two styles, of course no fruit could be expected. By not laying in the branches so close, and by removing all superfluous summer shoots, more light and air was admitted, and he had, in consequence, plentiful crops.

4591. Renovating old or decayed trees. Proceed as in renovating the plum.

4592. Protection from birds. "As cherries, in a ripening state, are frequently attacked by birds, it is advisable to have choice wall-trees or clappers defended with large nets in due time. Old fishing-nets may also be spread over the branches of dwarf standards. To protect other standard trees, let scaracrows and clap-boards be put up in terrorumm."

4593. Gathering the fruit. Use the hand, taking hold of the fruit-stalk, in gathering from the wall, and the cherry-gatherer, in gathering, from distant branches of high standards.

4594. Insects, dicusare, &c. Wall cherry-trees are often infested with the red spider, but standards are generally not much injured by insects. Naismith says, "our cherry-trees, both in the open air, and on the natural walls, particularly the tops of the young shoots, are much attacked with a small black insect, provincially called the black beetle. The remedy I have found most effectual for their destruction, is, a mixture of pitch, with one sixteenth part of powdered opium, one sixteenth part of sulphur, dissolved over a slow fire in an earthen pipkin, until they be well incorporated; when cold, divide it into small pieces, about the size of a hen's egg, and burn it under the trees with damp straw, directing the smoke as much as possible where the insects are most numerous. In an hour afterwards (if the state of the fruit will admit) give the trees a good washing with the garden-engine, which generally clears off the half-dead beetles, and prevents the spreading of the red spider." (Caled. Mem. ii. 96.)

Sect. III. Berries.

4595. Of the cultivated berries the gooseberry is the most useful species in Britain, in which it is grown in far greater perfection than in any other country; next to the goose-

tree is the currant, valuable as affording wine; besides these are included the mulberry, raspberry, strawberry, barberry, and elderberry.

Subsect. 1. Black, or Garden Mulberry. — Morus nigra, L. (Blackw. t. 126.)

Moneca Tetrandria, L. and Urticea, J. Martir, Fr.; Maubeurbam, Ger.; and

Mor, Ital.

4596. The black mulberry is a middle-sized tree, with a whitish bark, and broad, sub-

quinquefoliate, bluntish, and rugged leaves. It has generally male flowers or catkins, on the same tree with the fruit, which is a turbinate berry. Young trees from seed, Professor Martyn and Knight observe, often show nothing but male flowers for several years, and yet afterwards produce also female flowers, and become fruitful. The fruit of seedling-
trees, it is said, is the largest and best flavored. The black mulberry is a native of Persia, and it is supposed was brought to Europe by the Romans, as Pliny mentions two varie-
ties. It will not live in the open air in several parts of Sweden, and is treated as a wall-
tree in the north of Germany. It is mentioned by Tussor, in 1573, and was cultivated by Gerrard, in 1596. In some of the old kitchen-gardens near London, there are trees of a very great age, which are very healthy and fruitful. Bradley says, that most of these were planted in the time of James the First, who attempted unsuccessfully to set up a silk manufacture in England; but the species on the leaves of which silk-worms are fed, is the white mulberry (Morus alba), whose fruit is not of any value. Forsyth mentions "four large mulberry-trees as still standing on the site of an old kitchen-garden, now part of the pleasure-ground at Sion House, which the late Duke of Northumberland used to say were about three hundred years old." The mulberry is remarkable for putting out its leaves late, so that when they appear, which is generally in May, with the leaves of the common ash-tree, the gardener may take it for granted that all danger from frost is over. There is a curious tree formed by two stems proceeding from a fallen trunk on the site of the garden of the Abbey of St. Augustine at Canterbury, which must at least be 300 years old, probably much older. (Neill, in Hort. Tour, &c. p. 13.)

4597. Use. The fruit is brought to the dessert, and recommends itself by its highly aromatic flavor, and abundant subacid juice. It is very wholesome, cooling, and rather laxative. Like the strawberry, it does not undergo the aceto fermentation, and there-
fore may be safely eaten by gouty and rheumatic persons. An agreeable wine is made from the juice; a syrup is obtained from the unripe berries, which is used as a gargo in cases of sore throat; and the bark of the tree is a vermifuge.

4598. Varieties. Only one variety of the black is mentioned by Miller, with palmate leaves and smaller

fruit.

4599. Propagation. By seed, layers, cuttings, or grafting. The first is the least advisable mode, unless for stocks to inarch upon, because, though some affirm the fruit of seedlings to be the largest, yet the plants are very long of coming into bearing.

4600. By layers. "These will generally take root sufficiently the first year to bear segregating from the parent tree, and should then be planted in a nursery, and trained up with single stems. In four years they will be fit to plant out where they are to remain. They should be planted at a proper distance to admit the
sun and air, as the fruit, when the trees are too close, is very apt to turn mouldy; they should also be sheltered from the east, north, and west winds." Knight lays parts of the bearing branches of old trees, in pots set to these branches upon poles. Wood of any age will do, and the plants afford fruit the second or third year.

481. By cuttings. In raising mulberries from cuttings, choose the former year's shoots, having one joint of six to eight inches long. Plant them either in the open ground, six inches apart, and at the distance of two inches in the rows, leaving only two or three buds above ground; mulch the ground with leaves or dung well rotted, to keep it moist, and the plants will require little watering. If they succeed well, they may, next season, be transplanted into a nursery, and treated as directed for young trees, while they remain under the nursery, should be transplanted every three or four years. Miller says, mulberry cuttings will also strike well if planted on a hot-bed in spring.

482. Knight failed in raising cuttings on a hot-bed in spring, but was very successful by the following process. He cut vigorous shoots from the trees in November, and formed them into cuttings of about five inches length, with three or four leaves, and one or two buds of young growth. They were intended to be put in pots, and the bottom of each cutting was cut so much above the root, that its surface might be nearly parallel with that of the bottom of the pot in which it was to be placed. "The cuttings were then placed in the open ground, under a south wall, and so deeply immersed in it, that one bud only remained visible above its surface; and in this situation they remained till April. At this period the buds were much swollen, and the upper ends of the cuttings appeared similar to those of branches which had been shortened in the preceding autumn, and become incapable of transmitting any portion of the ascending juice. The bark at the lower ends had also begun to emit those processes, which usually precede the production of roots. The cuttings were now removed to the pots to which they had been previously fitted, and placed in a moderate hot-bed, a single bud only of each cutting remaining visible above the mould, and that being partially covered; and in this situation they vegetated with so much vigor, and emitted roots so abundantly, that I do not think one cutting in a hundred would fail with proper attention. The mould I employed was the alluvial and somewhat sandy loam of a meadow, which was sparingly supplied with water; and the plants, till they had become sufficiently rooted, were shaded during bright suns."

483. In Spain and India, as Townsend and Tenent inform us, the white or silk-worm mulberry is always propagated by cuttings, three or four being planted together, so as to grow up into a bush.

484. By suckers. Mulberry-trees, as well as most others so propagated, are longer of coming into bearing cuttings than into tree. The plants which arise from them, and those obtained from suckers or seed, have entire heart-shaped leaves, but those obtained from suckers or seeds present deeply divided or half-winged leaves.

485. By grafting. Knight having seen some young mulberry-trees in pots, raised them to the bearing branches of old trees, and grafted them by approach. The young grafts bore fruit the third year, and continued annually productive. This tree succeeds very ill by the common mode of independent grafting. (Hort. Trans. i. 40.)

486. The tree. The mulberry tree observes, delights in a rich light earth, and where there is depth of soil, as in most of the old kitchen-gardens about London. In a very stiff soil, or on shallow ground, whether of clay, chalk, or gravel; the trunk and branches are commonly covered with moss, and the little fruit produced is small, till tasted, and ripens late. Abercrombie says, the mulberry thrives well in a deep sandy loam, and will succeed in any fertile mellow ground, having a free situation in the full sun.

4607. Silic. The mulberry is generally grown as a standard or half standard, sometimes as espaliers, dwarfs, or wall-trees. A single young plant does not afford much fruit; but one full-grown and healthy, one will afford more than is sufficient for the supply of a large family. Miller recommends planting in a situation defended from the strong south and north-west winds, in order to preserve the fruit from being blown off; but at the same time to keep them at such a distance from trees or buildings, as not to keep off the sun, for which the fruit has not the benefit of his rays to dissipate the morning dew early, it will turn mouldy and rot upon the trees. The nurseries, and especially those at Paris, afford large standard trees of five or six years' growth, which come into bearing the year after removal. Those are in general to be made choice of in preference to raising the tree from cuttings, or inarching. In orchards they may be planted thirty or thirty-five feet apart from other trees, and twenty feet apart on walls or espaliers; dwarfs may be planted fifteen feet apart, and in each case temporary fruit-trees may be introduced between.

4808. Forsyth recommends planting mulberries in grass orchards and pleasure-grounds, because as the finest of the fruit, when ripe, frequently drops, it can be picked up without receiving any injury. Another reason for planting these trees on lawns or in orchards is, that, when full-grown, they are too large for a kitchen-garden. Abercrombie adds, "so nice is the criterion of perfect ripeness, that berries falling without damage are superior to those gathered. Besides, a grass surface harmonises best with trees of magnitude, and increases the beauty of a rural scene.

489. In these experiences, the fruit might be much improved in size and flavor by training the trees against a south or west wall. "The standard mulberry," he says, "receives great injury by being planted on grass-plots with the view of preserving the fruit when it falls spontaneously. No tree perhaps received so much maltreatment as the spice-rack. It was thought the fruit might be frequently dug up the roots, and occasionally assisted with manure. The ground under the tree kept free from weeds by treading the grass, particularly in the fruit when it ripened, as the reflected light and heat from the bare surface of the soil is thus increased; more especially if the end branches are kept pruned, as that portion of the tree in the nursery, should be transplanted every year. If the tree is trained as an espalier, within the reflection of a south wall or other building. If a wooden trellis were constructed with the same inclination as the roof of a forcing-house, fronting the south, and raised about six feet from the ground, leaving the soil with the same inclination as the trellis, a tree trained on it would receive its influence to great advantage, and would probably ripen its fruit much better than a standard." (Hort. Trans. ii. 92.)

4810. Knight concurs with Williams as to the advantages of planting the tree against a south wall in cold situations, adding, that "it affords an exception to all, or almost all other fruits, to which the wall gives increased bulk and beauty, at the expense of ripeness and flavor.

4611. Mode of bearing. "The mulberry produces its fruit chiefly on little shoots of the same year, which arise on last year's wood, and on spurs from the two-year-old wood; in both stages, mostly at the end of the shoots and branches."

4812. Pruning. Miller and Forsyth agree in saying there is no occasion to prune standards farther than to thin out irregular crossing branches, and never to shorten the young wood, on which the fruit is produced.
4613. Pruning wall-trees and espaliers. "Cut so as to bring in a partial succession of new wood every year, and a complete succession once in two years: taking the old barren wood out, as may be necessary. In the winter pruning, lay in the reserved branches and shoots at six or seven inches' distance."

4614. Williams observes, that the trained mulberry requires some nicety in pruning, otherwise it will not bear fruit. "The following method has succeeded in my garden for several years past. All the annual shoots, except the fore-right, are neatly trained to the wall, and these last must be left to grow till towards midsummer, and then be shortened about one third of their growth to admit light to the leaves beneath. With this object in view, all the shoots of August that have grown right shoot all the branches and leaves which they reach, and they must then be shortened nearer to the wall than before. In the month of March, or beginning of April, the ends of the terminal shoots should be pruned away down to the first strong bud that does not stand fore-right, and the front shoots which were pruned in August, must also be shortened down to two or three eyes. If trained after this method, the tree will afford fruit the third year; when the management of the fore-right shoots must be somewhat different. These should now be shortened at the end of the month of June or beginning of July, so as to leave one leaf only beyond the fruit, the terminal shoots being nailed to the wall as before, and left without any summer pruning; the fore-rights will not advance any further, as their nutriment will go into the fruit, which, when quite ripe, becomes perfectly black, very large, and highly saccharine."

4615. Knight remarks (Hort. Tr. iii. 63.), that the mode recommended by Williams may suit the ex- treme sub-tropical climate; and that in cold climates the mulberry-tree will be found to deserve a place on the south wall, little fruit will be produced, and that will ripen but ill, unless the bearing wood be brought closely into contact with the wall; and the great width of the leaves, and vigorous habit of the tree, present some difficulties to the cultivator, when this mode of training and pruning is adopted. It will be found necessary to diminish the luxuriant growth of the tree, and at the same time to increase its disposition to bear fruit. Such effects may, however, be readily produced by several different means; by destroying a small portion of the bark, in a line extending round the trunk or large branches, by ringing, by tying and long-continued ligatures, or by training the bearing branches almost perpendicularly downwards. I have adopted the last-mentioned method, because it greatly increases the disposition in the tree to bear fruit, without injuring its general health, and because it occasions a proper degree of vigor to be every where almost equally distributed."

4616. Season for pruning. "As the blossom-buds of the mulberry-tree cannot be readily distinguished from others in the winter, the best period for pruning is when the blossoms first become visible in the spring. Pinch off every barren shoot which is not wanted to cover the wall, and stop every bearing shoot, under similar circumstances, at the third or fourth leaf. Williams has correctly stated, that the bud immediately below the point at which a bearing or other branch is pinched off, usually affords fruit in the following year." Knight, in Hort. Trans. iii. 63.) The mulberry succeeds better than any other tree when trained downwards (fig. 494), either horizontally and dropping (a), or in the slanting manner (b).

4617. Renewing old mulberry-trees. Miller, Forsyth, and Knight, agree that this may be done with trees of any age, by remov- ing a part of the branches; or by completely heading down, and renewing the soil by fresh mould enriched by dung.

4618. Taking the crop. "The most forward berries attain maturity about the end of August; and there is a succession of ripening fruit on the same tree for about a month or six weeks; the ripening ber- ries gradually change, from a reddish to a black color, and should be gathered and made fit for market, one after another; this delicate fruit will not keep good off the tree above a day or two." Coke and Knight have had mulberries from wall and espalier trees in gathering from July to the end of October. (Hort. Trans. v. 494.)

4619. Forcing the mulberry. Knight observes, that "the mulberry is a much finer fruit when ripened under glass, in the north of Herefordshire, than in the open air; and in the still colder parts of England it is probably the only means by which it can be ripened at all. The culture of this fruit, by me, under glass, has been attended with great success: I have found, that, in this manner, a mulberry-tree which, under such circumstances, produces more abundantly, or which requires less care. Its blossoms set equally well in different degrees of heat, and the same continued temperature which will ripen the earlier varieties of the grape in the end of July, will afford perfectly ripe mulberries early in June; end a tree of the latter species, when fully loaded with fruit, presents at least as agreeable an object to the eye as many plants which are cultivated as ornamentals only. It is not subject, under common care, to any disease or injury, except the attacks of the red spider; and as the foliage and growing fruit of the mulberry-tree are not at all injured by being wetted every evening with clear water, the red spider can never prove a very formidable enemy."

(Hort. Trans. ii.)

4620. The barberry is a branchy prickly shrub, rising to the height of eight or ten feet, with ash-colored bark, yellow inside. The flowers appear in pendulous racemes towards the ends of the branches; the corolla, yellow; the berries at first green, but of a fine red when ripe. The flowers appear in May with a cowslip odor; and the fruit, which is of an acid flavor, ripens in September. It is a native of the eastern countries, and also of most parts of Europe, and is found in woods, coppices, and hedges in England, especially in a chalky soil. It is generally supposed that the Puccinia, a fungus which closes up the epidermis of the leaves of corn crops, and appears on their surface like rust, is generated by the Ecedium berberidis, an insect which inhabits the barberry. (Sir J. Banks on Blight, &c.)

4621. Use. The fruit is used for preserving, candying, and pickling, as well as for garnishing dishes; the plant is also an ornamental shrub, both when in flower and in fruit.
4622. Varieties. Those most esteemed for their fruit are the following, viz.

Red barberry without stones; which has no juice in the berries when fully ripe. It is only found without stones when the plant is of attained considerable age, and is on a poor soil.

White barberry. (Poit. et Turp. Fr.)

Black sweet; which is the tenderest of them, and should be planted in a warm situation.

Common red with stones. (Unkumpt. 1 p. 106. cited.) This is placed in the garden as an ornamental than use, on account of its beautiful red berries.

Purple-fruited. (Poit. et Turp. Fr. t. 59.

4623. Propagation. "All the varieties are propagated commonly by suckers, also by cuttings and layers of the young branches, and occasionally by grafting; the common red sort is also raised by seed; each of which methods of propagation may be performed in the spring; that by suckers and layers may be effected also in autumn."

4624. Soil and final planting. The barberry prefers a light dry soil. One or two plants may be planted in a complete orchard, and trained as standards; but where the shrubbery is the site, it may be allowed to grow as a bush or shrub. "According to the nature of the ground, plant either at any time from autumn to spring, or only in the spring; the plants may be already furnished with a head pretty well advanced, if thought proper; allow them square distances of from fifteen to thirty feet."

4625. Mode of bearing and pruning. The barberry produces its fruit at the sides of the branches in spring and summer. In the spring it bears both on young and old wood, chiefly toward the extremities. The branches should not be shortened, except the design be to force out new wood; permit the head to extend freely; and give only occasional pruning, to keep it in a pretty round form, open in the middle; cutting out dead, stunted, or superfluous suckers. Reduce the long ramblers, and trim up low stragglers, also lateral shoots on the stem, and eradicate all root-suckers."

4626. Taking the crop. "As a proportion of the berries ripen in the course of September, they will afford occasional gatherings for present use; and as they will be wholly ripe in October, all that are wanted for domestic supply should be then pulled; always pick them in bunches." (Abercrombie.)

4627. The common elder is a bushy tree of twelve or sixteen feet in height, much branched, and covered with a smooth grey bark, becoming rough on old stems. The leaves are unequally pinnate. The flowers appear in terminating cymes, and are succeeded by globular blackish-purple berries, mawkishly sweet. It flowers in May, and the berries ripen in July. The whole plant has a narcotic smell, and it is not prudent, we are told, to sleep under its shade. It is a native of Britain, and many other parts of Europe, and of Africa, Japan, &c. It is common in damp woods and hedges, and is sometimes introduced in cottage gardens and plantations for the fruit, and in forest plantations, exposed to the sea air, as a nurse plant.

4628. Use. The fruit is in demand in many places, but especially in London and the principal English towns, for making elder wine of the expressed juice; a powerful, warming, and enlivening article for the cotager. The tree, professor Martyn observes, is a whole magazine of physic to rustic practitioners, nor is it quite neglected by more regular ones. An excellent healing ointment is made of the green inner bark, which is also purgative in moderate, and diuretic in small doses. A decoction of the flowers promotes expectoration and perspiration, and they give a peculiar flavor to wine. The flowers are reported to be fatal to turkeys, and the berries to poultry in general. No quadruped will eat the leaves of this tree; notwithstanding it has its own phalana and aphis. The wood is used by the turner and mathematical instrument maker; and is made into skeaters for butchers, tops, angling rods, and needles for weaving nets.

4629. Varieties. Miller mentions several, but those cultivated for their fruit are chiefly the white and black. The scarlet and green berried may also be used like the black, and are very ornamental trees in the shrubbery.

4630. Site and soil. "As the tree will grow anywhere, either in open or shady situations, it may be planted in a cut-out ground, or waste spot, in single standards or in rows, to assist in forming boundary fences. Trees planted in the hedge order, if suffered to grow up untrimmmed, will produce abundance of berries for use."

4631. Propagation and rearing. "The elder is raised by cuttings of the young shoots in the spring, and by seed in the autumn. Select for cuttings some strong young shoots of last summer, cut into lengths of one foot, and thence to three feet or more: these may be planted either where it is intended the plants should remain, or in a nursery for a year's growth. Insert them from six to fifteen inches into the ground, according to their length; they will soon strike root; and will shoot strongly at top the same year. Train those designed for standards with a single stem from three to five feet high; and those for hedges, with branches out from the bottom. To raise this tree from seed; sow in autumn, October, or November, or later in mild weather, or soon in the spring, either for a hedge, in drills, where the plants are to be trained into a cord or hedge, after one or two years to the length desired; or from slips, where plants are to be used as standards."

4632. Final planting. "Standards may be planted from ten to twenty feet apart. They should be allowed to shoot out above to form a branchy head, nearly in their natural order: in which they will soon become plentiful bearers. For hedge-planting, insert cuttings or year-old plants into the sides or tops of banks or ditches, or other suitable boundary lines, a foot or two. Permit them to branch out from the bottom where they are designed for full fruiting, merely cut in the sides a little regular below, leaving them to run up above in branchy growth, for producing large crops of berries."

The purpose of making wine, about the middle and end of September, and in October, and should then be gathered in bunches." (Abercrombie.)

4634. The gooseberry in Piedmont, where it is found wild, and the berries catable, but astringent and neglected, is called grisselle. Some derive our name gooseberry from grisselle, or the resemblance of the bush to gorse; others, as Professor Martyn, from its being used as a sauce with young or green geese. Gerrard says, it is called feaberry (feverberry) in Cheshire, and it has the same name in Lancashire and Yorkshire. In
Norfolk this term is abbreviated to seabbes, or, as they pronounce it, fapes. Carberry is another British name for this fruit. The gooseberry-bush is a low, branching, prickly shrub, with trilobate sub-pubescent leaves, one-flowered nodding peduncles, and pendulous berries, hairy or smooth. It is a native of several parts of Europe, and abounds in the Vallaies in copsewoods, where it produces a small, green, hairy, high-flavored fruit. In England it is naturalised in various places on old walls, ruins, and in the woods and hedges about Darlington. It is cultivated in greater perfection in Lancashire than in any other part of Britain; and next to Lancashire, the climate and treatment of the Lothians seem to suit this fruit. In Spain and Italy the fruit is scarcely known. In France it is neglected and little esteemed. In some parts of Germany and Holland the moderate temperature and humidity of climate seems to suit the fruit; but in no country is its size and beauty to be compared with that produced in Lancashire, or from the Lancashire varieties cultivated with care in the more temperate and humid districts of Britain. Neill observes, that when foreigners witness our Lancashire gooseberries, they are ready to consider them as forming quite a different kind of fruit. Happily this wholesome and useful fruit is to be found in almost every cottage garden in Britain; and it ought to be considered a part of every gardener's duty to encourage the introduction of its most useful varieties in these humble enclosures. In Lancashire, and some parts of the adjoining counties, almost every cottager who has a garden, cultivates the gooseberry, with a view to prizes given at what are called gooseberry-prize meetings; of these there is annually published an account, with the names and weight of the successful sorts, in what is called the Manchester Gooseberry-Book. The prizes vary from 10s. to £5 or £10. The second, third, to the sixth and tenth degrees of merit, receiving often proportionate prizes. There are meetings held in spring to "make up," as the term is, the sorts, the persons, and the conditions of exhibition; and in August to weigh and taste the fruit, and determine the prizes. In the gooseberry-book for 1819 is an account of 186 meetings; the largest berry produced was the top-sawyer seedling, a red fruit, weighing 26 dws. 17 grs. Forty-six red, thirty-three yellow, forty-seven green, and forty-one white sorts were exhibited, and fourteen new-named seedlings, which had been distinguished at former meetings, stated as "going out," or about to be sold to proprietors.

4635. Use. The fruit was formerly in little esteem; but it has received so much improvement, and it is now considered very valuable for tarts, pies, sauces, and creams, before being ripe, and when at maturity it forms a rich dessert fruit for three months; and is preserved in sugar for the same purpose, and in water for the kitchen. Unripe gooseberries can be preserved in bottles of water against winter; the bottles are filled with berries close corked and well sealed; they are then placed in a cool cellar till wanted. By plunging the bottles, after being corked, into boiling water for a few minutes, (heating them gradually to prevent cracking,) the berries are said to keep better. (Neill.)

4636. Varieties. The gooseberry is mentioned by Turner in 1573. Parkinson enumerates eight varieties, and the largest, gran, one of red, one of yellow, and one of the pearl gooseberry; but Rea has the blue, several sorts of yellow, the white Holland, and the green. Miller only says, there are several varieties obtained from seed, most of them named from the persons who raised them; but as there are frequently new ones obtained, it is needless to enumerate them. The proper and lusty shrubbery, shown at 60 to 100 sorts, is the growth of the Lancashire growers above 500. Forsyth, in 1800, mentions ten sorts as common; and adds a list of forty-three new sorts grown in Manchester. The following may be considered established varieties, and such as merit cultivation:—

4637. Selection of sorts. "It must be admitted," Neill observes, "that although the large gooseberries make a fine appearance on the table, there are often deficient in flavor when compared with some of smaller size. Many of them have very thick strong skins, and are not edible unless thoroughly ripened. Some of the large sort, however, are of very good quality, such as the red gage and the green walnut. Among these also Wilmot’s early red deserves further notice. It was raised by Wilmot, at Isleworth, in 1804, and has been cultivated by him very extensively on account of its valuable properties; being early ripe, of excellent flavor, and extremely productive. It usually ripens from the middle to the end of June. For culinary use in the month of May it is larger and better than most others, the skin has less gum, and the whole berry melting to a fine consistency." Neill also recommends cultivating the early and late sorts, in order to prolong the season of this fruit. In Lancashire, the Warrington or Manchester red, which is an improved variety of the old ironmonger, is esteemed the best dessert fruit; and the shoots growing upright, the shrub occupies less horizontal space than most varieties. The warrington red they consider the best sort for preserving. The best mode to obtain a complete collection is to send to a Lancashire nurseryman, stating whether the object desired is an assortment of large showy sorts, a numerous variety, or a selection of the most useful sorts: but all the sorts worth having as dessert or kitchen fruit, are in the London and Edinburgh nurseries.

4638. Propagation. The gooseberry may be propagated by all the modes applicable to trees or shrubs; even by pieces of the roots; but the mode by cuttings, is usually adopted for continuing varieties, and that by seeds for procuring them.
By seeds. As far as we know, the scientific mode of impregnating one variety with another has not been applied to this fruit. In general, the seed of some choice variety thoroughly ripe is taken and sown in boxes or pans of rich soil kept in a greenhouse. If good seed is used, the plants can be had a year old they are planted out in nursery rows, to be cultivated and trained there a year or two; in general they will bear the third year.
